SIMILAR EFFECTS ON TOMATO PLANTS OF *Azotobacter* INOCULATION AND APPLICATION OF GIBBERELLINS

By Dr. R. M. JACKSON, MARGARET E. BROWN and SUSAN K. BURLINGHAM

Rothamsted Experimental Station, Harpenden, Hertfordshire

INOCULATION of seeds or seedlings of several kinds of crop plant with *Azotobacter* cultures can increase yields significantly[1–3]. Earlier flowering of wheat following *Azotobacter* treatment has also been observed by us and other workers[4,5]. Experiments with tomato (*Lycopersicum esculentum*) have now shown that, although the final yield of fruit may not be affected, *Azotobacter* treatment advances early growth and flowering.

Shaken liquid cultures of *Azotobacter chroococcum* were grown for 14 days in a nitrogen-deficient medium with sucrose as the carbon source (no sucrose remained at the end of the incubation period). Tomatoes, variety 'Money Maker', were treated either by allowing the seed to imbibe in the undiluted culture for 1 h before sowing in unsterilized potting compost, or by dipping the roots of seedlings into the culture before transplanting. Control seeds or seedlings were treated with nitrogen-deficient medium without added sucrose.

During growth, the plants were given nutrient solution at fortnightly intervals. They were graded for leaf number and length, height to growing point and first flowering truss, and for flower and fruit development, fruit ripening and yield. Developmental curves were constructed for each flowering truss by assigning a value to each stage of flowering and plotting the total score against time. Fig. 1 shows flowering curves of inoculated and control plants.

Seed or root inoculation significantly accelerated internodal stem elongation and leaf development during the first weeks of growth (Table 1), but as the first truss developed these effects became less. Treated and control plants produced the same number of leaves before the first flower buds appeared. Flower and fruit formation on the first truss were advanced by a week or more (Fig. 1), but the fruits neither ripened faster nor did their final yields differ from those of untreated plants. The second and third trusses developed sooner on treated than on untreated plants but by only 2–4 days. Four additional weekly applications of *Azotobacter* culture to plants grown from treated seed had no further effect.

These developmental effects closely resemble those resulting from application of gibberellins to tomato plants. Rappaport[6] found that single applications of 2·5–50 μg of a mixture of gibberellins 1 and 3 to the first expanding leaves increased internode length during early growth. Repeated treatments with small doses produced no further

* Denotes significance at 5 per cent level.

effects, but with more than 25 μg per plant leaves often became abnormal. Flowering was hastened by 3–6 days without affecting the number of nodes; fruit set was rapid but ripening was poor.

Because of these similarities we compared *Azotobacter* inoculation and treatment with gibberellic acid. Gibberellic acid was applied to the seeds or roots of 5·0, 0·05 or 0·005 μg per plant. Table 1 shows that the early growth effects on tomatoes from 5 μg gibberellic acid and from *Azotobacter* inoculation were similar, except that 5 μg gibberellic acid produced leaf abnormalities and *Azotobacter* treatment did not. Smaller amounts of gibberellic acid had no significant effect. Most data on the effects of gibberellic acid come from treatments applied to growing plants. A report of seed treatment[7] suggested that concentrations below 5·0 per cent do not affect tomato growth; 5 μg per seed, which produced significant effects in our experiments, was equivalent to a 0·3 per cent concentration of gibberellic acid. The small effects produced by 0·05 μg gibberellic acid were not statistically significant.

Gibberellic acid and indolyl-3-acetic acid have been detected in *Azotobacter* cultures[8,9]. Cultures of the *Azotobacter* strain used in our experiments were assayed for both these growth regulators. Indolyl-3-acetic acid was found in amounts that increased from 0·05 μg/ml. in a 2-day-old culture to 1 μg/ml. in a 30-day-old culture. The method of extraction and chromatography described by Katznelson *et al.*[10] also detected gibberellins in small quantities, which increased with increasing culture age. Chromatograms were cut into sections and eluates from these tested for gibberellin-like substances on dwarf pea plants[11]. Internodal extension was significantly accelerated by eluates from sections of the chromatogram corresponding to the marker gibberellic acid, also by eluates from an unknown substance at R_F 0·85–0·9 in isopropanol/ammonia/water (10 : 1 : 1). The latter substance gave a pale green fluorescence after spraying with 3 per cent methanolic sulphuric acid[12]; the gibberellic acid spot from the *Azotobacter* cultures did not fluoresce because this method will not detect less than 5 μg.

Three mechanisms have been proposed to explain the effects of *Azotobacter* on plant growth: (1) nitrogen fixation; (2) antagonism towards pathogenic or toxin-producing soil organisms; (3) the production of growth regulators in the rhizosphere. Our results provide some evidence for the third mechanism, although it has yet to be determined whether the effects described are caused by the gibberellin-like substances formed by *Azotobacter* in the culture fluid, or in the rhizosphere, or by other micro-organisms that produce growth-promoting substances and are stimulated to grow by *Azotobacter*. There is no evidence that indolyl-3-acetic acid causes the growth effects we describe.

SELECTION FOR HOST PREFERENCE IN *Anopheles gambiae*

By M. T. GILLIES*

East African Institute of Malaria and Vector-borne Diseases, Amani, Tanganyika

IN certain parts of Africa, notably Swaziland and Southern Rhodesia, the application of residual insecticides to houses has led to an apparent change in behaviour of the main vector of malaria, *Anopheles gambiae* Giles, from resting indoors and biting man to resting outdoors and feeding on cattle or other animals. Two explanations have been advanced for this situation: (*a*) that two sibling species of the *A. gambiae* complex may originally have been present in the area, one of which was eliminated owing to its domestic habits and consequent greater opportunity of coming into contact with chemically treated surfaces; (*b*) that there has been a change in behaviour within a single species due to selection by the insecticide[1]. Active research into the validity of the first possibility is going on at present, the available evidence suggesting that in this area, at least, there has been a replacement of one form of the *A. gambiae* complex by another[1]. However, the possibility of the occurrence of true behavioural changes within a single form of the species cannot be ignored, and with this object in mind an attempt was made to alter the feeding preferences of the species by artificial selection in the laboratory.

It should be stressed that the preference shown by a particular species of mosquito for one mammalian host or another is likely to be strongly influenced by environmental conditions. In experimental work, particularly, it is obvious that the manner in which the hosts are presented can profoundly influence the feeding responses of hungry mosquitoes. Because of this, only comparative data can be obtained and no special significance should be attached to the actual proportion feeding on one host or the other in a particular set of experiments. Furthermore, to obtain reliable information it is necessary to compare the behaviour of two strains of mosquito simultaneously. This avoids the effect of temporary or secular changes in the relative attractiveness of the two hosts as well as of other uncontrollable elements in the experimental set-up.

Selection experiments were carried out at Muheza in the coastal lowlands of northern Tanganyika in 1962–63, starting with eggs from a pool of wild-caught females. *A. gambiae* is known to be highly anthropophilic in this area, cattle and other domestic animals being largely absent[2,3]. No treatment of houses with residual insecticides had been carried out at any period. Previous observations had shown that form *A* of *Anopheles gambiae* (= Group *A* of Davidson and Jackson[4], Species *A* of Paterson[5]) was present in the district. As described

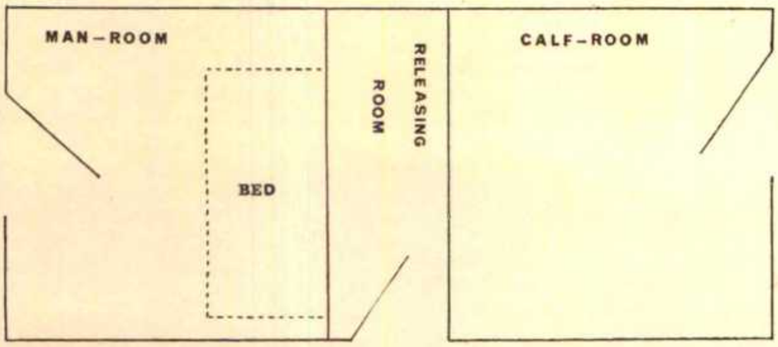

Fig. 1. Diagram of experimental hut used for selection experiments with *Anopheles gambiae*

here, it was confirmed at the end of the experiments that only one form of the complex was involved.

The technique adopted was based on the experiments of Hadjinicolaou[6], working in Southern Rhodesia, who had found that when *A. gambiae* females from different sources were released at night inside a large mosquito net containing a human volunteer and a calf, consistent differences in the feeding behaviour of the two strains could be detected. In the work recorded here the method was modified by using a specially built experimental hut of mud and thatch, containing two separate, partly communicating rooms in which the baits slept. The lay-out of the hut is shown in Figs. 1 and 2. The outside walls were 6 ft. 6 in. high, ventilation being provided by open eaves 4 in. high all the way round, which were screened off with netting to prevent the escape of mosquitoes. The dividing walls of the releasing room were of mud up to a level of 4 ft., the space above that being closed with netting except for a gap of 4 in. at the top which was left open to provide the mosquitoes with free access to both the other rooms. The whole hut was fitted with a cotton ceiling to prevent them flying up into the thatch. One room contained a bed on which an adult man slept, while the other was provided with a bedding of dry grass for the calf.

The two strains of mosquitoes used in each test were marked with coloured dusts before release so as to make possible their subsequent identification. They were introduced into a cage with a sliding lid and placed in the releasing room during the course of the afternoon. They were released at about 9 p.m. local time after both baits had settled down for the night. The sleeper wore shorts and a shirt and was allowed to cover himself with a thin cotton sheet, previous experience having shown that this covering did not prevent hungry mosquitoes from feeding. The insects were caught by hand in the morning after the baits had left, and the numbers of gorged specimens collected in each room recorded. The validity of the method, as a means of assessing host preference, depended on the assumption that the mosquitoes had actually fed on the occupant of the room in which they were caught and not simply flown across from the other room. Precipitin tests, done on stomach smears of females that were not used for breeding purposes, showed that 6·8 per cent of 369 mosquitoes from the calf-room had fed on man, while 2·3 per cent of 709 from the man-room were positive for ox blood. Assuming that both lines showed the same degree of mobility, it follows that the true total of females feeding on man was something like 4·5 per cent higher than the figures given in Tables 1 and 2 suggest. Mixed feeds amounted to less than 0·5 per cent of the total tested. Thus relatively little movement was occurring, and it may be concluded that the room catch gave an accurate picture of the feeding preference of the mosquitoes under test.

Only those caught in the man-room or calf-room and with fresh blood in their stomachs were retained for egg-laying. An outdoor insectary was built adjacent to the hut. This was divided into two separate sections, one for each selection line, each completely screened and entered by a separate door from the exterior. At the beginning of the experiments eggs from females caught in houses from the surrounding district were obtained, and the females that emerged from them were released in the experimental hut. This represented the parental generation. On recapture they were divided into parental-man and parental-calf strains, according to the room in which they had been caught, and returned to the insectary for egg-laying. The eggs they laid represented the F_1 generation of the two lines, the adult females of which were then released and treated in the same way. In each generation the mosquitoes were tested as soon after emergence as possible, usually when 1–3 days old, although older females were occasionally used. During this period they received sugar-water only.

Two series of experiments were conducted, 6–7 generations being reared and tested in the first and 4 in the second. Each series ran for a period of 5–6 months, since, although each generation only took 2–3 weeks to come through, difficulties were encountered in rearing the larvæ in adequate numbers, so that it was necessary to get repeated egg-batches from the same females after testing. The calf strain was rather more refractory in this respect, and in both series the man strain tended to get a generation ahead of it. Consequently it was not always possible to compare the behaviour of the same generation in the two strains.

The results of the experiments are shown in Tables 1 and 2. In order to simplify the tables only the percentage of those caught in the calf-room is shown separately. 4·1 per cent of the overall total of fed females were collected in the releasing room. Routine precipitin tests were made on all of these throughout the first series, and those positive for ox blood (about one-third of the releasing-room catch) have been added to the appropriate calf-room catches shown in Table 1. It will be seen from the results that by the F_2 a well-marked difference between the two lines had developed in the proportion caught in the calf-room. This was maintained during tests on the F_3. At this stage selection of the calf line was relaxed for a generation so as to use all the females for building up the numbers to an adequate level. When selection was resumed with the F_5 it was found that the difference in behaviour had virtually disappeared. However, in the F_6 a clear-cut difference had again developed between the two lines. It will also be seen

† Estimated for the differences in behaviour between the two lines for each generation tested.

that there were significant differences in behaviour between the F_4 and F_5 of the man strain when tested against the parental stock. In a second series the difference in behaviour only became apparent in the fourth generation, on which only 5 replicate tests could be made before the experiment had to be terminated. However, it may be noted that in all 5 releases the calf strain showed a relatively higher proportion feeding on the calf than did the man strain. Thus, taking both series together, it is clear that within a very few generations it was possible to select out strains that differed significantly in the preference shown for feeding on man rather than on a bovine.

At the end of a series of experiments both lines were crossed with each other and the hybrid males that resulted were found to be fully fertile. Thus it appeared that both selection lines belonged to the same mating group. Further tests showed that the man line was fully interfertile with the 'Kisumu' laboratory strain, and without grossly distorted sex-ratios in the hybrids, and so belonged to Group *A* of the *A. gambiae* complex[4].

A number of points should be raised in connexion with these results. First, the fact that the feeding preferences of both lines often varied in the same direction from one test to the next, or from one generation to the next, provided ample evidence of the sometimes overriding importance of external factors, of which temperature and wind direction were probably the most important. Secondly, since the heritable component of host selection might be relatively slight compared with environmental effects under experimental conditions, it follows that negative results in a particular series of experiments would be of little significance. Thirdly, a difference in behaviour between the two lines was elicited after surprisingly few generations, despite the fact that selection could only be applied to the females. It is concluded that the experiments described give support to the view that natural populations of the form of *Anopheles gambiae* studied show some degree of polymorphism for host preference, thus providing a basis on which natural or artificial selection for behavioural changes can operate.

I thank the Malaria Eradication Division of the World Health Organization for a grant towards the cost of constructing the experimental hut and insectary used in this work. I also thank Dr. B. Weitz of the Lister Institute of Preventive Medicine, Elstree, Herts., for carrying out a large number of precipitin tests on stomach smears of mosquitoes used in the experiments, and also Dr. P. F. Mattingly for reading the manuscript. Mr. S. A. Magayuka and Mr. A. Sabuni helped in carrying out routine catches, etc.

PHYSICS

Theory of Striations in Gas Discharges

So far, a satisfactory theory for the well-known phenomenon of striations in gas discharges has proved elusive[1]. This communication delineates the basic elements of a theory for the stationary striation with a fuller account to be offered later encompassing the moving variety as well[2]. The central mechanism has been provided in relation to the manifestation of Liesegang rings[3], which represents the underlying regularity producing repetitions of nodes and antinodes proposed earlier by Morgan[4]. While the two physical phenomena entail entirely different processes, it happens that the analytical formalisms are very much alike. Indeed, the non-stationary striation has no equivalent in the formation of periodic precipitates, involving as it does much more complex processes.

A signal outcome of the present theory is the explanation of Goldstein's law[5] relating the spacings of the stationary striations l with the ambient pressure p:

$$l \propto p^{-m} \qquad (1)$$

where m is very nearly 1/2. In an analogous development of the governing Poisson equation as for the Liesegang phenomenon[3], it can be shown that the spatially periodic behaviour of the potential as well as the electron distribution entail the vital Debye-length λ_D so that the spacing between striations obeys:

$$l \propto \lambda_D, \; \lambda_D^2 = \frac{kT}{4\pi n q^2} \qquad (2)$$

where all quantities have their usual meaning. Hence, it is more sensible to associate the distance between striations with the carrier density n, that is, $l \propto n^{-1/2}$. The temperature dependency is somewhat involved for partial ionization but can be described in terms of the Saha equation; for complete ionization a $T^{1/2}$ dependence arises.

The connexion between l and the pressure itself is not as direct since it very much depends on the nature of the gas and its degree of ionization. For simple gases like hydrogen, it may be seen that:

$$P = (n_n + 2n)kT \qquad (3)$$

where n_n denotes the number of neutral atoms per unit volume and $n = n_i = n_e$, n_i and n_e being the related concentration of the ions and electrons, respectively. In the limit of a strongly ionized system, $n_n \rightarrow 0$ and P is just proportional to n, whereby it follows that $m \sim 1/2$, but not precisely so for departures from complete ionization.

Since striations have been customarily observed in weakly ionized gases, it may be well to assess the question of incomplete ionization more fully. For simple systems such as:

$$A \rightarrow A^+ + e \qquad (4)$$

let N be the total neutral particle density which admits:

$$n = \frac{P}{kT} - N \qquad (5)$$

From equation (2), it follows that:

$$\lambda_D^2 = \frac{kT}{4\pi q^2 \frac{P}{kT}\left(1 - \frac{NkT}{P}\right)} = \frac{(kT)^2}{4\pi q^2 \, . \, P}\left(1 - \frac{P_0}{P}\right)^{-1}, \quad P_0 = NkT \qquad (6)$$

Since $1 > P_0/P > 1/2$ over the entire range of ionization:

$$l \propto \lambda_D \simeq \frac{kT}{2\sqrt{\pi}\, q P^{1/2}\left(1 - \frac{1}{2}\frac{P_0}{P}\right)} \qquad (7)$$

which accounts for slight departures of m from 1/2 even for weakly ionized gases; the formula has no meaning for $P = P_0$.

Clearly, it is far simpler to relate the spacings of the striations directly with the electron density, and in this regard the spacings can be either too large or too small for visual observation. In discharges having an ambient temperature somewhat below 1,000° K, an electron density of $n = 10^{14}$/c.c. would have striations spaced a fraction of 1 mm apart. At $n = 10^{20}$/c.c., the expected separation would be about 10^{-7} cm. In any event, intermediate ranges of electron density are essential for ready detection of the striation phenomenon.

It has been tacitly supposed that the periodic luminous appearance of the discharge somehow reflects the spatial fluctuations of the electron density. Without necessarily entering into the details of the recombination process ultimately leading up to the emission of radiation, at some stage associated with the release of photons:

$$\frac{dn_i}{dt} = \frac{dn_e}{dt} = -k n_i n_e \qquad (8)$$

Hence, since the photon production relates to an intensity

$$I \propto \frac{dn_i}{dt} \qquad (9)$$

a periodic variation in I will result so long as n_e itself is periodic.

Perhaps it should be mentioned that the reaction rate equation (8) may not merely be representative of volume recombination but also of the radiative step in the three-body mechanism recently discussed by D'Angelo[6]. The latter appears more favourable than the dissociative recombination process formerly viewed as dominating over direct volume recombination.

A further interesting aspect is next noted regarding the distinctness of the striations in terms of the electron density. The presence of a large number of electrons tends to enhance light output while simultaneously providing a greater variation of intensity across the width of a striation. But as already mentioned, high concentrations of carriers produce a bunching or crowding of the striations. Thus the periodic glow of a discharge is optimizable.

As for the Liesegang phenomenon[3], non-linear effects may arise in which strict periodicity of the striations fails to occur. Our present description applies in the linear limit. The non-linearity will be covered in a more comprehensive development incorporating the non-stationary behaviour[2].

A Hydrogen Singing-flame Ionization Detector

The sensitivity of an ordinary hydrogen flame ionization detector to hydrocarbons has been found to be two to three times higher when the detector flame 'whistles' or 'sings'. Further investigation of this phenomenon has disclosed the probable reasons for the enhanced sensitivity and has uncovered other useful characteristics of the singing-flame detector. 'Singing' hydrogen diffusion flames were first noted more than 160 years ago[1], shortly after the discovery of hydrogen. A number of investigators[2,3] have since investigated the characteristics of such flames; however, no practical application of this unusual phenomenon appears to have been made.

A drawing of a hydrogen flame ionization detector of the type used in the present investigation is given in ref. 4. However, the rod electrode was replaced by a cylindrical platinum gauze electrode surrounding the burner tip in order to improve the ion-collection efficiency. Sample gases containing known concentrations of propane in nitrogen were used for calibration. With the optimum hydrogen and air flow rates, the ionization detector in both the singing and quiescent stages gave a linear response up to at least 15,000 p.p.m. propane in nitrogen. However, the ion current from the singing flame was 2·7 times higher than with the normal detector flame over the entire range of propane concentrations.

Of primary interest is the reason for the greatly enhanced sensitivity of the detector when resonating. Time exposure photographs of our detector flame showed it to be spherical when quiescent and elongated when singing. In 1866, Töpler[5], using stroboscopic methods, found that the singing hydrogen diffusion flame was, in fact, an oscillating flame. Drawings of his observations are given by Gaydon and Wolfhard[6]. In brief, Töpler's work showed that each oscillation was caused by a small flame at the burner orifice growing into a tongue of flame which separates from the burner tip and burns out; a small flame remains in the burner orifice for the next cycle. The output from our singing-flame detector was shown on a cathode ray oscilloscope to have a periodic waveform with a frequency of about 1,600 c/s, the same as that of the emitted note. Higher ion production in the singing flame, therefore, probably results because the flame surface area is larger and because the vibrating flame is ejected clear of the burner tip, thereby preventing quenching of the flame at the burner rim as occurs with the normal diffusion flame.

Besides the increasing sensitivity of the singing-flame detector, which would be particularly useful for trace hydrocarbon analysis, the wave-form output of the detector also makes it amenable to a.c. amplification with its inherent advantages (stability, cost, compactness, etc.) over d.c. amplification. The rectified output of the singing-flame detector is exceptionally steady in contrast to the erratic response of a turbulent or premixed flame[7].

Energy Gap of β Silver Selenide

An interesting variation of apparent measured intrinsic band gaps of β (low temperature) silver selenide prepared by different methods has been noted. Melt-grown silver selenide has been determined to have a band gap of 0·04–0·1 eV at about 300° K[1,2]. When prepared as a powder at temperatures under 100° C[3] silver selenide has a gap of 0·07–0·1 eV. This same silver selenide when sintered at 200° C (above the β–α phase transition) for 15 min and then remeasured in the same temperature range exhibits a different band gap, 0·2 eV.

Another method developed by us in which basic solutions of silver and selenium are reduced by hydrogen at pressures in excess of 2,000 lb./in.^{2} at temperatures of approximately 200° C yields silver selenide having an apparent band gap of 0·2 eV that remains constant on sintering at 200° C.

Measurements on silver selenide prepared by the two methods were carried out in the same manner. Powder samples were compacted into pellet form (1·27 cm diameter with thickness up to 0·4 cm) using pressures of 70,000 lb./in.^{2} and the electrical resistivities and Hall effects were measured using the Van der Pauw technique[4] in the range of temperature from $1,000/T = 4$ to about 2·7/°K.

Our results tend to confirm the statements of Simon *et al.*[2] (who investigated melt-grown silver selenide) that the use of Hall or electrical resistivity measurements as a function of temperature in the range of temperatures from $1,000/T$ of 4 to 2·6/°K tend to give slopes from plots of $\ln RT^{3/2}$ versus $1,000/T$ or $\ln \rho$ versus $1,000/T$ which, assuming no degeneracy and intrinsic conditions, are not readily interpretable in terms of simple intrinsic energy gaps.

While Simon *et al.*[2] have mentioned the difficulty in associating a definite meaning to 'energy gap' determinations, they have not mentioned a factor which may influence the interpretation of the slopes determined as above, namely, the effect of dissolved silver, that is, the electrical state of small amounts of silver in the β silver selenide lattice. It is conceivable that the changes in the silver concentration change the Fermi level and that the actual band gap remains constant. Our results above may suggest that the state of silver in the silver selenide could change on undergoing a phase transition, and, as inferred in previous publications[5,6], the role of silver either in undergoing a phase transition or the change in solubility with decreasing temperature may give rise to precipitation of silver (especially on cooling) or to silver in interstitial sites. It is suggested that the effect of excess silver and its role in the lattice could account for the different 'activation energies' observed, especially as varying degrees of order or disorder in the lattice are possible.

RADIOCHEMISTRY

Thermal Annealing of Tellurium resulting from Isomeric Transition in Solid Sodium Tellurate

Little attention has hitherto been directed to the chemical effects of radioactive decay in ionic crystals. Two papers are devoted to β-decay. Baro and Aten[1] have examined the distribution of arsenic-77, formed by β-decay of germanium-77 in GeO_2, between tri- and penta-valent states, and Andersen and Knutsen[2] the distribution of antimony-125, formed by β-decay of tin-125 in K_2SnCl_6. In both papers a small annealing effect has been reported. The yield of arsenic and antimony in the pentavalent state increased on heating. Campbell[3] has found that on heating sodium bromate crystals containing bromine-80*m* the distribution of bromine-80 resulting from isomeric transition is not changed.

In this communication experiments are described which show that thermal annealing does influence the yield of tellurium-127 as Te(IV) and Te(VI) from isomeric transition of tellurium-127*m* in labelled sodium tellurate.

The $Na_2{}^{127m}TeO_4$ crystals were prepared using tellurium dioxide irradiated for 6 months with a neutron flux of 10^{12} n cm^{-2} sec^{-1}, and then cooled for another 6 months. Almost all the activity was that from the tellurium-127*m* (103 days) → tellurium-127 (9·3 h) pair. The active tellurium dioxide was dissolved in 30 per cent sodium hydroxide, and the sodium tellurite oxidized with 15 per cent hydrogen peroxide. The fresh crystals of sodium tellurate, which had been precipitated while heating the solution, were washed with cold water and ethanol, then dried *in vacuo* and kept for two days at liquid air temperature. After two days they were subjected to thermal annealing treatment, followed by dissolving in cold 4 N hydrochloric acid and separation of the Te(IV) and Te(VI). This separation was done by extraction with 20 per cent tributylphosphate in kerosene from 4 N hydrochloric acid solution. The yield of ^{127}Te(IV) was determined by a well-known method, which consists of comparing the organic phase activity measured immediately after the extraction with that of an aliquot of the parent solution taken before extraction.

In Fig. 1 the retention (that is, the yield of ^{127}Te(VI)) is plotted against the time of heating at 20° ± 0·1° C, 60° ± 0·1° C, 120° ± 1° C and 190° ± 2° C. It can easily be seen that the retention increases quite markedly at the higher temperatures, the plateau being reached within 10–15 min. Even at 20° C the annealing effect can be observed; however, the ΔR value in this case is comparatively low (about 7 per cent), and the plateau is reached more slowly (within 1 h).

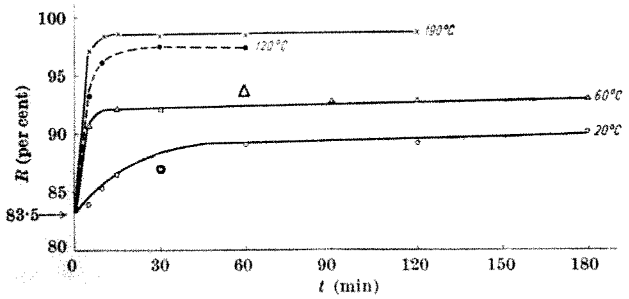

Fig. 1

Investigations of the chemical effects following isomeric transition in solids seem to be of interest, since in this case there are no radiation-induced defects in the crystals. Moreover, applying external irradiation with ionizing radiation, electrons, etc., the defects can be introduced in a well-controlled way. Experiments along these lines are being continued.

METALLURGY

Low-temperature Alloy Synthesis

The low temperature reduction of metal ions to the finely divided free metal by sodium borohydride reduction has been reported recently[1]. In addition, the preparation of a number of inter-metallic compounds from mixed salt solutions using boiling hydrazine and hypophosphorous acid solutions as reducing agents has been accomplished[2]. It was of interest to examine the sodium borohydride reduction of solutions of two metal ions as a possible method of low-temperature synthesis of finely divided solid solution alloys. Such materials would be of particular interest in catalyst investigations, where high-surface area alloys are often difficult to obtain. Work on such reactions have, therefore, been carried out, using metals where alloy formation might reasonably be expected with suitable preparative conditions. Those chosen for initial investigation were combinations of platinum–gold, platinum–iridium, and palladium–gold. All three metals form face-centred cubic lattices, have atomic radius ratios well within the Hume–Rothery limit, and form solid solutions with each other over the entire composition range.

Table 1. Chemical and X-ray Data for Alloy Formation

Compositions (Atom %)		Unit cube dimensions (Å)*		Composition corresponding to experimental lattice spacing
Starting solutions	Reduced powder	Experimental	Literature	
Pt-40 Au	Pt-39·9 Au	3·970	3·982 (ref. 3)	Pt-32 Au
Pt-60 Au	Pt-63·0 Au	4·016	4·017 (ref. 3)	Pt-62 Au
Pt-80 Au	Pt-77·2 Au	4·036	4·038 (ref. 3)	Pt-75 Au
Pt-40 Ir	Pt-19·6 Ir	3·906	3·900 (ref. 4)	Pt-12 Ir
Pt-60 Ir	Pt-36·1 Ir	3·896	3·885 (ref. 4)	Pt-26 Ir
Pt-80 Ir	Pt-61·0 Ir	3·901, 3·848	3·865 (ref. 4)	Pt-82 Ir, Pt-19 Ir
Pd-50 Au	Pd-47·8 Au	4·013	3·971 (ref. 5)	Pd-70·5 Au

* Those values given in *kx* units have been changed to Å by the conversion factor 1·002.

The procedure followed for all syntheses consisted of adding 2·0 ml. of a mixed salt solution to 20·0 ml. of 1·85 M sodium borohydride solution at 50° C. The total salt concentration was held at 0·5 M, with the individual salt concentrations adjusted to the ratios shown in column 1, Table 1. The chloride salts were analytical reagent grade and the sodium borohydride was of 98+ per cent purity. All solutions were made with demineralized water. Additions were made in a steady stream from a pipette, while stirring the borohydride solution. In every instance a vigorous reaction occurred and a black precipitate formed immediately. The powders thus obtained were separated by centrifugation and washed thoroughly in 3·7 M sulphuric acid and water.

It was found that these systems indeed formed alloys by the foregoing procedure. Determination of their unit cube-lengths by X-ray diffraction and of their compositions by chemical analysis confirmed, in the case of platinum–gold, near stoichiometric alloy formation. As shown in Table 1, the compositions of these powders were within ±5 per cent of the starting solutions. Furthermore, the lattice spacings agreed, within their experimental error of ±0·2 per cent, with the chemical compositions. Thus complete alloy formation is indicated. As an example, the nominally 60 atom per cent gold alloy analysed chemically as 63 atom per cent gold. Our lattice spacing of 4·016 Å is in excellent agreement with the literature value for 63 atom per cent gold of 4·017 Å (ref. 3), and corresponds to a composition of 62 atom per cent gold, well within the experimental error. The other two powders also exhibited stoichiometric reduction with the expected precision, although the nominally 40 atom per cent gold sample apparently contains some free gold in addition to the alloy phase. As confirmation of the foregoing results with platinum–gold, physical mixtures of these two metals were examined by X-ray diffraction and gave two sets of peaks corresponding to the 3·914 Å lattice spacing of platinum and the 4·078 Å spacing of gold.

The platinum–iridium and palladium–gold powders, in contrast to platinum–gold, showed alloys the compositions of which did not agree with their original salt solutions. The nominally palladium-50 atom per cent gold, although analysing as 47·8 atom per cent gold, gave a lattice constant corresponding to 70·5 atom per cent gold. Thus unalloyed palladium was also present in the powder. The platinum–iridium systems uniformly showed lower than stoichiometric reduction of iridium and alloys of still lower iridium content. The nominally 80 atom per cent iridium sample in addition showed two sets of X-ray patterns, formed by a platinum-rich alloy and an iridium-rich alloy.

The varying results obtained with the three systems studied can be qualitatively understood in terms of two characteristics of the reduction reaction. First, the metal salts vary widely in their reactivity with sodium borohydride. We have observed the reduction rates of the single metals to be in the order $\mathrm{Pt} \simeq \mathrm{Au} > \mathrm{Pd} > \mathrm{Ir}$. Thus the near stoichiometric reduction and alloy formation of platinum–gold is due to the nearly equal reduction rates of these two metals. On the other hand, iridium, reduced much more slowly than platinum, is less likely to enter the lattice during crystal growth than is platinum. Hence a platinum-rich alloy is the result. Unalloyed iridium continues to be formed following completion of platinum reduction, but only until the borohydride is spent. This brings up the second pertinent property, the catalysis of borohydride hydrolysis by certain metals. Brown and Brown[1] reported a catalytic order of $\mathrm{Pt} > \mathrm{Ir} > \mathrm{Pd}$. We have confirmed this and also found that gold is still less active than these three. Since platinum is an excellent catalyst for the hydrolysis, the borohydride, even though initially present in large excess, is exhausted before all the slowly reactive iridium ions are reduced. In the case of palladium–gold, neither metal is an active hydrolysis catalyst and complete reduction of both metal ions is achieved. However, owing to the more rapid reduction of gold, the alloy formed is rich in this component and free palladium is, therefore, also present.

Surface area measurements by nitrogen adsorption gives areas of approximately 5 m^2/g. Using this number, an average particle size of about 600 Å is calculated. Attempts to fix this number by X-ray line broadening yield 50 Å as the average particle size. However, this latter method is uncertain since the line broadening may be due to some inhomogeneity in the alloy. Chemical and spectroscopic analysis of these samples revealed no significant impurities other than several tenths of one per cent oxygen as surface oxide. Boron, which might be expected to form metal borides or be present as an adsorbed impurity, was found in less than 10 p.p.m. concentration.

Tests of the generality of this technique are in progress. Preliminary results indicate that platinum forms alloys with non-noble transition metals such as cobalt and nickel, and also with copper. Other combinations of noble and non-noble metals are also being investigated.

This research is part of the Energy Conversion Project sponsored by the Advanced Research Projects Agency, Department of Defense. The work was carried out under contract *DA*–36–039 *SC*–89156 through the U.S. Army Electronics Research and Development Laboratories.

CHEMISTRY

Theory of the *p*H-stat Titration of a Polyfunctional Reactant by a Competitive 'Ligandee'

IN their recent extensive investigation of the reversible reaction of deoxyribonucleic acid (DNA) and bivalent mercuric compounds[1], Yamane and Davidson[2] introduced a useful new kind of *p*H-stat titration which they applied both to their investigation of the DNA–Hg^{II} interactions and to the examination of DNA–Ag$^+$ interactions[3].

Their results with Hg^{II} taken together with earlier investigations[1,4] have since been used as the basis of a mechanism for the reaction of this ion with double-stranded polynucleotides[5,6].

Although the purpose of their *p*H-stat investigations was different, it is intuitively clear that this kind of *p*H-stat titration can, in many cases, provide desirable quantitative information with relatively simple means, so I have thought it worth while to derive the theory of the titration.

Experimentally, one adds a small amount, ΔM_t moles, of the metal salt to an unbuffered solution of the polyfunctional reactant (or polyvalent ampholyte) at a predetermined *p*H. If the salt or its ions release protons into the solution, it can be back-titrated with hydroxyl ion to restore the original *p*H—thereby determining (by equivalence) a quantity ΔH_r. The ratio of these two quantities (constant temperature and pressure being understood) is, in the limit, equal to $(\partial H_r/\partial M_t)_H$, where the symbols are: H_r, concentration of hydrogen ion released; M_t, total added metal concentration; H, hydrogen ion concentration of the solution (maintained constant as described).

More generally, M_t need not be a metal ion but can be any kind of chemical species which is bound by a macromolecule. A good deal of verbiage can be saved by referring to the entity which is bound as the 'ligandee'.

If the ligandees do not interact, that is, if each ligandee is bound independently of the others, one can show that:

$$\left(\frac{\partial H_r}{\partial M_t}\right)_H = \frac{\sum^{m} \dfrac{a_i H^{a_i} K_i [D_i]}{(H^{a_i} + K_i M_f)^2}}{1 + \sum^{m} \dfrac{H^{a_i} K_i [D_i]}{(H^{a_i} + K_i M_f)^2}} \tag{1}$$

which is implicitly a function of:

$$M_t = M_f + \sum^{m} \frac{K_i M_f [D_i]}{H^{a_i} + K_i M_f} \tag{2}$$

The symbols not yet defined are: M_f, the free concentration of that ligandee which is added; a_i, the stoichiometric coefficient corresponding to the equilibrium:

$$D_i + M \rightleftharpoons D_i M + a_i \mathrm{H}^+ \; ; K_i \tag{3}$$

in which D_i is a binding site (ligand) of type i, M is the ligandee and K_i may be called the 'stoichiometric' intrinsic constant. It differs from the conventional intrinsic constant[7] in that its *p*H dependence (so far as stoichiometry is concerned) is explicitly stated. The remaining symbols are: D_i, the concentration of sites of type i; m, the total number of kinds of sites.

If the approximation of independent sites can be sustained, equations (1) and (2) are undoubtedly applicable to the binding of Ag$^+$ by DNA (ref. 3). The expressions for the binding of Hg^{II} by DNA (or polynucleotides) are somewhat more complicated because both CL$^-$ (if HgCl$_2$ is used) and OH$^-$ 'bind' Hg^{++} as well as DNA.

From the form of (1) and (2), it is obvious that in favourable cases (that is, when $a_i \neq 0$) the *p*H-stat titration itself may be used to determine the K_i. It is also obvious on physical grounds that the 'skyline' type of curve which results experimentally[3] when $(\partial H_r/\partial M_t)_H$ is plotted versus r (where r is defined as moles Hg^{II} or Ag$^+$

added per mole nucleotide; not to be confused with the subscript r on H_r which stands for 'released') is implicit in the set (1) and (2). Thus, a_i determines the maximum possible height of the 'buildings' as well as its presence ($a_i \neq 0$) or absence ($a_i = 0$); D_i determines their width and the K_i determine both the squareness (K_i large) and whether the 'buildings' merge into one another (two or more K_i of similar value) or are distinct (K_i or greatly dissimilar value). The set (1) and (2) is quite capable of reproducing the step-function used previously in discussing the mechanism of the Hg^{II}–DNA reaction[5,6].

Especially when the binding is very strong, as in the case of Hg^{II} and DNA, there is a definite heuristic advantage in plotting the results as $(\partial H_r/\partial M_t)_H$ versus r (rather than versus M_t). Such a plot facilitates the determination of a mechanism, as evidenced in detail by its recent use[6] in the mechanism proposed for the reaction of Hg^{II} and double-stranded polynucleotides. These remarks apply equally well to the case of Ag$^+$ and DNA.

The theory is by no means restricted to DNA or to macromolecules, but applies quite generally to those numerous situations in solution chemistry in which an added reagent (the ligandee, M, or a molecular form containing it) competes for a site on a polyfunctional reactant normally occupied by another ligandee (in the particular case of DNA, protons). The advantages of carrying out the experiment at constant pH are, no doubt, readily apparent to those engaged in the investigation of the interaction of ligandees and biological macromolecules, polyelectrolytes, and the like.

Electron Spin Resonance Investigations of Ultra-violet and X-irradiated Bovine Serum Albumin

WE have already reported[1] that the radicals of methionine produced by X-rays at room temperature may be quenched by ultra-violet light. Corresponding investigations with bovine serum albumin show a quite different behaviour, and initial results with this substance are now reported.

Polycrystalline native bovine serum albumin (Behring Werke, Marburg, Germany) with a bulk volume of 540 cm^3/100 g was sealed under vacuum ($< 10^{-3}$ torr) and irradiated at room temperature. The electron spin resonance measurements were carried out under the same conditions. The irradiation with X-rays was carried out with a 180-kV source (half-value layer : 0·90 mm copper, dose-rate : 450 r./min, dose : 100 kr.). The irradiations with ultra-violet were performed with a mercury low-pressure lamp (*NN* 15/44, Quarzlampengesellschaft, Hanau Germany), which emits mainly in the 254 mμ line or with a mercury high-pressure lamp (*Q* 700, from the same firm). The ultra-violet light from the latter was filtered with a 2-mm filter-glass of the type *WG* 5 (Schott and Gen., Mainz, Germany) to give only ultra-violet of longer wave-lengths ($\lambda > 300$ mμ). The intensity of the low-pressure lamp and of the high-pressure lamp at the sample tube amounted to 9×10^3 ergs cm^{-2} sec^{-1} and $1 \cdot 1 \times 10^4$ ergs cm^{-2} sec^{-1} respectively. The electron spin resonance spectra were recorded with a Varian spectrometer which operates in the X-band. To avoid saturation effects in the irradiated sample the microwave energy of the klystron was sufficiently attenuated (20 db). All the other technical details are described in the aforementioned publication[1].

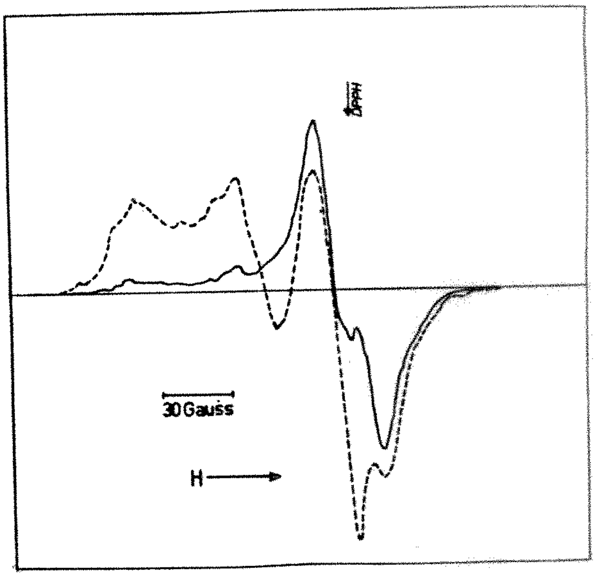

Fig. 1. Electron spin resonance spectra of irradiated bovine serum albumin. The spectra represent the first derivatives of the actual absorption curves. —, 100 kr.; – – –, 100 kr. + 5 h ultra-violet ($\lambda = 254$ mμ)

After irradiation of the bovine serum albumin, an electron spin resonance signal was obtained (Fig. 1, solid line) which is composed of a sulphur pattern and an unresolved doublet, described already by other authors[2,3]. The radical concentration of the X-irradiated bovine serum albumin was $3 \cdot 6 \times 10^{17}$ spins/g. For technical reasons, the X-irradiated samples could not be measured immediately after irradiation; they were stored for several hours at −17° C. On exposing the X-irradiated bovine serum albumin to ultra-violet from the mercury low-pressure lamp, the radical concentration increased immediately. By this process the X-ray induced signal was altered. With increasing irradiation time the spectrum became more and more 'cysteine-like' (Fig. 1, dotted line). On exposing bovine serum albumin only to 254 mμ-light, practically the same electron spin resonance pattern was observed. The results of these investigations do not give any information about the behaviour of the X-ray induced radicals under the influence of the 254 mμ-light. Therefore further experiments were carried out with ultra-violet of longer wave-lengths ($\lambda > 300$ mμ), which alone do not lead to any radical state detectable with our spectrometer. By the same irradiation a signal could only be detected in the presence of oxygen.

The irradiation with ultra-violet of longer wave-lengths does not alter the radical concentration of the X-irradiated bovine serum albumin (Fig. 2, upper curve, open circles and open triangles ; the two different signs stand for two sets of investigations under the same conditions). The slight decrease of the concentration with increasing irradiation time coincided with the radical decay of a control, which was only irradiated with X-rays (Fig. 2, open squares).

In the X-irradiated control, the maximal amplitude of the doublet showed the same decrease as the radical concentration (Fig. 2, upper curve, full squares). On the other hand, the signal-amplitude of the X-ray and ultra-violet irradiated bovine serum albumin led to a stronger decrease (Fig. 2, lower curve, full circles and full triangles). At the same time, the spectrum in the region of the lower

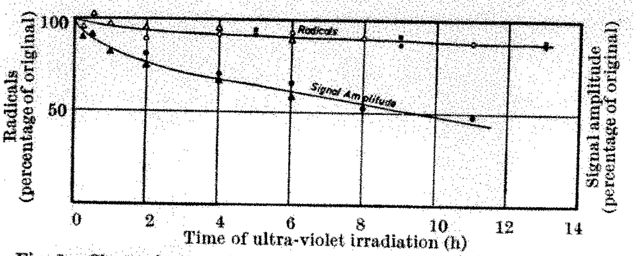

Fig. 2. Change in the relative radical concentration (open circles and triangles) and in the relative maximal signal-amplitude (full circles and triangles) in X-irradiated bovine serum albumin after exposure to ultra-violet of longer wave-lengths ($\lambda > 300$ mμ). The open squares and the full squares represent the time dependence of the radical concentration and the signal-amplitude respectively of a control which was not exposed to ultra-violet

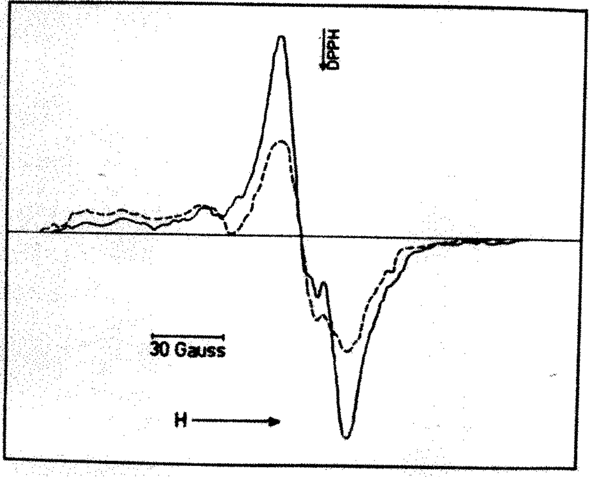

Fig. 3. Electron spin resonance spectra of irradiated bovine serum albumin. The spectra represent the first derivatives of the actual absorption curves. ——, 100 kr.; – – –, 100 kr. + 8 h ultra-violet ($\lambda > 300$ mμ)

magnetic field strength increased (Fig. 3; compare the solid line with the dotted one). This effect is not very large, but we believe that the site of the radical which gives rise to the doublet is shifted by the additional energy from the ultra-violet light. The irradiation with ultra-violet of 254 mμ and of longer wave-lengths formed also sulphuretted hydrogen.

This communication is dedicated to Prof. Brinkman (Groningen) on the occasion of his seventieth birthday.

Thermal Decomposition of Barium Azide

The rate of decomposition of solids is a function of the rates of: (1) nuclear formation; (2) propagation of the reaction outwards from the nuclei. Both these components might be expected to be influenced by external stimuli. The formation of nuclei by bombardment of the solid with α- or β-particles, or by irradiation with ultra-violet light, X-rays and γ-rays should be possible in favourable circumstances, and by the same agencies the rate of propagation of the reaction might be accelerated. For example, the effects of pre-irradiation by high-energy γ-rays (~ 1 MeV) on the subsequent thermal decomposition of the permanganates of sodium, potassium, rubidium, cæsium and silver are to shorten the induction period and accelerate the reaction[1]. It was of interest, therefore, to examine the effect of pre-irradiation by γ-rays on the isothermal decomposition of barium azide. There have been several previous investigations of the effects of radiation on barium azide. Pre-irradiation with α-particles[2], X-rays[3], and ultra-violet light[4] accelerates the rate of subsequent thermal decomposition, but to our knowledge no study has been made of the effect of γ-rays.

Fig. 1 illustrates the pressure-time plot for the decomposition of dehydrated barium azide crystals pre-irradiated with ~ 1 MeV γ-rays. The decomposition of the unirradiated salt is also shown. It is noted that the induction period is practically eliminated and the acceleration of the decomposition is increased. The salt after irradiation was buff colour.

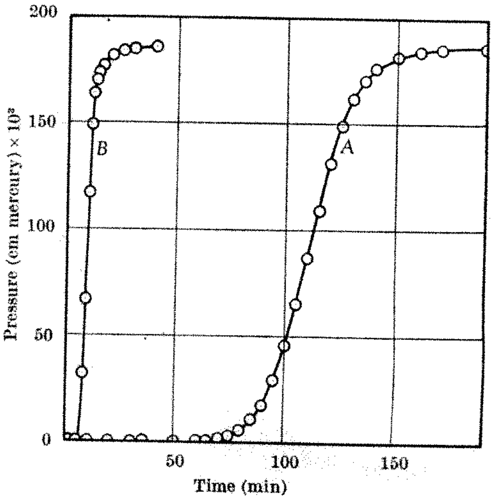

Fig. 1. Effect of pre-irradiation on thermal decomposition of barium azide. γ-ray dose, 20 Mrads; temperature of decomposition, 125° C. Curve *A*, unirradiated; curve *B*, irradiated

The pressure, p, after a time, t, for the decomposition of unirradiated dehydrated barium azide crystals has been given by Wischin[5] as:

$$p = Ct^x \tag{1}$$

where the value of x varied between 6 and 8. Thomas and Tompkins[6] introduced a correction, y, for the slow growth of nuclei when the pressure of nitrogen, expressed as a function of time of heating, t, is given by:

$$p = \text{const.}\ (t - y) \tag{2}$$

An analysis of random nucleation at potential nucleus sites, followed by three-dimensional growth, leads to the Avrami–Erofeyev[7] equation:

$$-\ln\ (1 - \alpha) = (k_1 t)^n \tag{3}$$

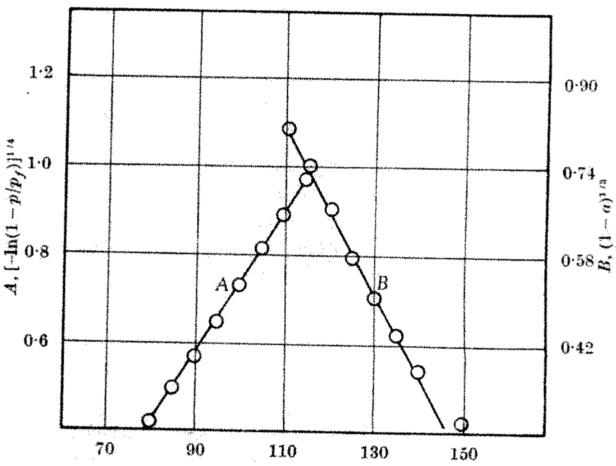

Fig. 2. Analysis of curve *A*, Fig. 1. Line *A*, $[-\ln(1 - p/p_f)]^{1/4}$ versus t; line *B*, $(1 - \alpha)^{1/3}$ versus t

where k_1 is a constant, and $\alpha = p/p_f$, where p_f is the final pressure.

We have applied the Avrami–Erofeyev equation to our pressure-time plots for the decomposition of unirradiated barium azide and find that with $n = 4$ the equation describes the acceleratory period excellently in the range 110°–140° C. The decay stage of the reaction is best described by the contracting sphere formula[8]:

$$(1-\alpha)^{1/3} = k_2 t + \text{const.} \qquad (4)$$

A typical analysis is shown in Fig. 2.

The activation energies calculated from the variation of the constants k_1 and k_2 with temperature are 26·8 and 24·3 kcal mole^{-1} respectively. The plots of log $k_{1,2}$ versus $1/T°$ K are shown in Fig. 3.

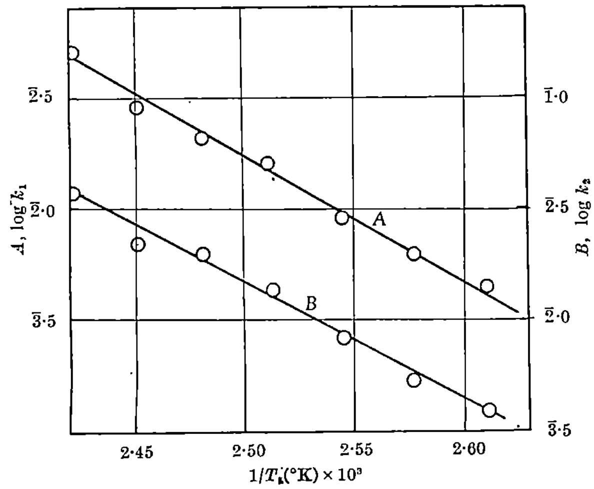

Fig. 3. Line A, log k_1 versus $1/T$(°K); line B, log k_2 versus $1/T$(°K)

We thank the South African Council for Scientific and Industrial Research for financial assistance, and Messrs. African Explosives and Chemical Industries for a research fellowship held by one of us (D.J.M.).

A more detailed account of this work, together with further observations, will shortly be published elsewhere.

BIOCHEMISTRY

Extracts of Mould-infected Groundnut Samples in Tissue Culture

During recent years the toxicity of groundnut ingredients in feed rations has presented a general problem. It was soon discovered that the toxic effect is due to aflatoxins, produced by certain strains of *Aspergillus flavus* growing on groundnuts[1]. Up to now, however, research workers have failed to establish a practicable method for the elimination of the toxicity of infected groundnut batches. Therefore, methods enabling the demonstration of aflatoxin are of great importance partly for the identification of infected batches and partly for the determination of the non-toxic ratio of groundnut ingredient in the feed.

In the Tropical Products Institute, London, and in four other institutions in Great Britain, biological and chemical methods have been evolved for the assay of toxicity of groundnut samples[2]. Biologically, the samples are tested by feeding the toxic extracts to day-old ducklings. The degree of toxicity is estimated on the basis of mortality rate or liver lesions resulting from the toxic effect. The chemical test is based on the ultra-violet fluorescence of aflatoxins. The intensity of fluorescence is determined on aflatoxins separated by paper chromatography.

Platt *et al.*[3] injected extracts of groundnut samples into embryonated hen's eggs and found that the presence of toxin was indicated by the death of the embryo.

Here the demonstration of aflatoxins was attempted with the tissue culture inoculation technique.

Toxic extracts were obtained by the method of Sargeant *et al.*[4]. From the groundnut samples aflatoxins were extracted with methanol and purified by partition first between chloroform and water and next between methanol and petrol ether.

The purified extract was chromatographed with the ascending technique, using Whatman No. 1 paper and n-butanol/acetic acid/water solvent (4 : 1 : 5 by vol.).

The methanol fraction was inoculated to calf kidney monolayer cultures in amounts 0·5 ml. per tube. The results were read after 48 h of incubation. Toxicity was evaluated by the degree of cell destruction caused in the tissue cultures. As a control, extracts prepared in the foregoing way from non-infected groundnuts were used.

The extracts of groundnut samples infected with *Aspergillus flavus* proved remarkably cytotoxic to calf kidney tissue cultures. In the affected cells both cytoplasm and nucleus were destroyed.

If 1 ml. of the extract was equivalent to 10 g of groundnut cake, toxin concentrations of 0·1–0·5 p.p.m. caused cell destruction up to a dilution of 10^{-4}, and those higher than 0·5 p.p.m. up to a dilution of 10^{-5}. In the samples aflatoxin concentration was determined by the fluorescence test. The non-infected extracts used as control had no toxic effect on calf kidney tissue culture.

The petrol ether fraction was also examined in tissue culture. It was found that, in comparison with the methanol fraction containing aflatoxins, the cytotoxicity of the petrol ether fraction was about 0·1 of the former. It was demonstrated that the petrol ether fraction contained no aflatoxins and its toxicity was due to certain lipid-like components of the metabolic products of fungi.

From the methanol fraction, aflatoxins were separated by paper chromatography. The fluorescent spot was eluted with chloroform and assayed for toxicity in tissue culture. Chromatographic spots having R_F values higher ($> 0\cdot 8$) or lower ($< 0\cdot 8$) than aflatoxins were examined in a similar way. Substances with R_F values lower than that of aflatoxins proved non-toxic, whereas those with higher R_F values exhibited similar toxicity. Since the extracts of non-toxic groundnut samples have no toxic effect on calf kidney tissue, it is obvious that the toxic substances present in chromatographic spots other than aflatoxin are also metabolic products of fungi. Information on the biological role of these substances has as yet been inadequate, but it seems likely that it may also have lethal effect on the chick embryo.

Our results are indicative that besides aflatoxins other substances have a role in the cytotoxic effect of mould-infected groundnut samples. Nevertheless, as the extracts obtained from non-infected samples caused no cell destruction in calf kidney monolayer cultures, the tissue-culture test appears to give reliable information on the mould contamination and aflatoxin content of groundnut batches. Further examinations are in progress concerning the determination of the toxic titre of aflatoxin concentrations and the nature of the other cytotoxic agents present in infected groundnut samples. Further to this, comparative studies are being conducted on the toxin production of *Aspergillus flavus* and other moulds.

Determination of the Aflatoxins

We report a new chemical method for determining the aflatoxins and, in particular, aflatoxin B_1. Previous methods have depended on the measurement of fluorescence[1,2] and are subject to certain errors, for example, quenching by impurities. Moreover, it is known that the fluorescence of solutions of aflatoxin B_1 in methanol varies with time[3].

All four aflatoxins have an ultra-violet absorption peak of high molar extinction at 363 mμ (ref. 4). The measurement of the optical density of this peak was chosen as the basis of an alternative assay procedure. This method is less sensitive than that depending on dilution to extinction of fluorescence, but it provides a more reliable means of assaying meals containing 1 p.p.m. or more of aflatoxin.

A brief outline of the procedure follows.

Groundnut meal (40 g) was extracted for 6 h with light petroleum (40°–60° C) in a Soxhlet extractor, dried and re-extracted for 6 h with methanol. The methanol solution was diluted with half its volume of distilled water, and continuously extracted with chloroform for 6 h. The residue from evaporation of the chloroform was made up to 10 ml. in chloroform, and 0·2 ml. portions of this solution were applied in a line across the bottom of a 'Kieselgel *G*' chromatoplate (thickness 750μ). This was developed in diethyl ether, dried and developed twice more in chloroform (2 per cent methanol). The chromatoplate was viewed under ultra-violet light (principal wave-length 365 mμ) and rejected if the bright blue fluorescent band of B_1 was not reasonably straight, clear of other fluorescent bands and running ahead of brown material near the origin.

The B_1 fluorescent band was then scraped from the chromatoplate treated for 5 min with cold methanol, the solution filtered and the silica washed with methanol. The methanol filtrate was made up to 5 ml. and the amount of B_1 calculated from the optical density of the solution at 363 mμ (ε 363 mμ = 22,000)[4].

In practice the ultra-violet spectrum was measured from 210 to 400 mμ on a recording spectrophotometer. A criterion of purity was obtained from the resemblance of the spectrum to that of pure B_1.

A number of extractions were made of a homogenized batch of groundnut meal which is being used as a standard for chemical and biological work. Several determinations were carried out on each extract, and the aflatoxin B_1 content of the meal was found to be 10·2 ± 0·19 p.p.m. (95 per cent confidence limits). Aflatoxin B_2 was detected as a second blue fluorescent band running behind B_1[4,5]. The amount present was determined by pooling the extract of this band obtained from several plates and was estimated as 0·2 p.p.m. in the original meal. The completeness of the removal of aflatoxin by 6 h Soxhlet extraction was checked by extraction of the meal for a further 6 h with methanol; this yielded no more B_1 or B_2. The possibility of loss of B_1 in the stages after the methanol extraction was checked by the addition of known quantities of pure B_1 to methanol extracts of the standard toxic meal and of a non-toxic meal and assay of the resultant products. There was good agreement between the found and calculated values for these samples.

The foregoing method has also been used for the determination of aflatoxins B_1 and G_1 in crude crystalline aflatoxin isolated from both synthetic media and sterilized groundnuts inoculated with *Aspergillus flavus*.

We thank Mr. A. B. Wood for the measurement of the ultra-violet spectra.

An Ion-exchange Method for the Estimation of Strontium-90 in Milk

The classical method of Bryant *et al.*[1] for the estimation of strontium-90 in milk is both tedious and hazardous. Davis[2], Farabee[3] and other workers[4,5] have all reported separations of strontium from calcium using ion-exchange methods, and such techniques would appear to offer promise for the estimation of strontium-90 in milk.

In the investigation recorded here, ion-exchange columns 22 cm long and 1 cm in diameter of the sodium form of 'Zeo-karb 225' (52–100 mesh) were set up and the resin conditioned by the passage of three bed volumes of a 2 per cent solution of the disodium salt of EDTA at pH 5. The flow rate through the column was limited throughout the investigation to three bed volumes per hour.

Samples of milk ash (10 g) were dissolved in 10 M nitric acid, inert strontium carrier (50 mg) added and the mixture heated until evolution of brown fumes ceased. 5 M sodium hydroxide was added until alkaline, the paste dissolved in 10 per cent EDTA solution (100 ml. disodium salt) and the pH adjusted to 5·00 with 5 N hydrochloric acid.

The solution of ash was passed down the column, which was washed with a 2 per cent solution of EDTA (disodium salt, 200 ml.) at pH 5·25 and, finally, with distilled water (200 ml.). The strontium was eluted from the column with 5 N hydrochloric acid (70 ml.), followed by distilled water (100 ml.). The total eluate volume was reduced to less than 100 ml. by evaporation and the pH adjusted to 5 by the dropwise addition of 5 M sodium hydroxide. After heating to 80° C, '880' ammonium hydroxide (3 ml.) was added, followed by an excess of ammonium carbonate solution. After cooling to room temperature the suspension was centrifuged, the supernate discarded and the precipitate washed several times with distilled water. The precipitate was dissolved in the minimum volume of 6 M nitric acid and inert yttrium carrier (10 mg) added. The solution was left to stand for 14 days[6] to allow the yttrium-90 daughter to grow in.

The solution was made alkaline with carbonate free ammonium hydroxide, the time noted and the precipitate coagulated by heating on a water bath. The suspension was centrifuged, both precipitate and supernate being retained. The precipitate was dissolved in the minimum volume of 6 M nitric acid, diluted to 10–15 ml. and the yttrium reprecipitated with ammonium hydroxide. After centrifuging (the supernatant liquid being added to that obtained earlier), the precipitate was again dissolved in the minimum volume of 6 M nitric acid. The solution was heated to 80° C and the yttrium precipitated by the addition of an 8 per cent aqueous solution of oxalic acid (20 ml.). The precipitate was rendered granular by heating on a water bath for 10–15 min, and after cooling to room temperature was filtered off through a 1·5 cm No. 42 Whatman filter paper mounted in a 'Perspex' filter. The precipitate was washed several times with distilled water, then with three portions of methanol (each 10 ml.) and sucked dry. The filter paper with the precipitate was secured to an aluminium counting tray with a little Gelva adhesive and the yttrium-90 decay followed for at least 60 h to establish radiochemical purity using a Philips's low-level counting assembly[7]. Strontium recovery was assessed gravimetrically by precipitation as carbonate from the combined supernates remaining after the precipitation of yttrium as hydroxide. The calcium content of the milk powder was determined by precipitation as oxalate. The amounts of strontium-90 in seven milk samples (chosen for their differing degrees of contamination) were determined in duplicate and the results corrected for decay from the time of sampling. The results were expressed as 'strontium units', that is, as picocuries of ^{90}Sr/g calcium. Yttrium recovery was assessed by detaching the filter paper and precipitate from the counting tray with a few drops of methanol, heating in a porcelain crucible at 850° C for 2 h and weighing as yttrium oxide.

The results are given in Table 1, and in Table 2 are compared with those obtained from other samples of the same milk powders in which strontium-90 had been determined using the nitric acid method.

Table 1

Sample No.	Sr recovery	Y recovery	% Ca	Strontium units
1*a*	90·79	87·10	15·28	6·8

5*a*	90·10	88·70	15·89	19·8
b	89·71	86·29		19·2
6*a*	90·79	88·70	15·92	24·8
b	89·97	89·51		24·5
7*a*	89·51	91·94	15·81	33·9
b	90·79	92·74		34·3

Table 2

Sample	Strontium recovery		Strontium units in sample	
No.	This method	HNO_3 method	This method	HNO_3 method
1*a*	90·79	88·0	6·8	6·9
b	90·44	89·62	6·7	7·2
2*a*	91·65	77·04	13·5	13·0
b	88·69	75·87	13·3	13·4
3*a*	89·04	88·58	14·8	14·5
b	86·13	89·63	14·7	14·5
4*a*	90·91	80·19	16·2	16·1
b	91·96	42·07	16·5	16·2
5*a*	90·10	88·93	19·8	19·5
b	89·71	78·90	19·2	19·8
6*a*	90·79	78·09	24·8	24·3
b	89·97	81·35	24·5	25·1
7*a*	89·51	87·66	33·9	34·6
b	90·79	87·65	34·3	34·8

It can be seen that the method is accurate, more rapid and less hazardous than that of Bryant and is easily adapted to analyse many samples concurrently.

Our thanks are due to Dr. R. F. Phillips, head of the Department of Applied Chemistry, Loughborough College of Technology, and to Stewarts and Lloyds, Ltd., for a scholarship for one of us (D. S.).

Effect of *N*-Ethylmaleimide on the Starch-liquefying Enzyme from Soy-flour

Information regarding soy-bean enzymes catalysing the breakdown of starch is contradictory or at best conjectural. The biological function of amylases in soy-beans is obscure as the beans contain very little starch. The consensus of opinion seems to be that soy-bean seeds are a good source of β-amylase. While some workers[1–3] feel that soy-beans contain no or only traces of α-amylase, Teller's investigations[4] and evidence from the effects of soy-flour on starch-viscosity measurements[5–7] point to the presence of a starch-liquefying enzyme in non-germinated soy-beans. Recently[8], the presence of a starch-liquefying and of a starch-saccharifying enzyme in soy-flour was demonstrated by differential thermal inactivation. This communication deals with the effect of the SH-blocking reagent *N*-ethylmaleimide (NEMI) on the starch-hydrolysing enzymes of soy-flour. It is known[9] that none of the α-amylase so far investigated contains free sulphydryl groups essential for enzymatic activity. β-Amylase purified and crystallized from soy-beans has been reported[10] to contain —SH groups essential for enzymatic activity.

Starch hydrolysis by 0·2 per cent calcium chloride extracts of soy-flour[8] (centrifugates of 10 per cent suspensions shaken for 1 h) was followed by determining both reducing sugars (by the ferricyanide method) and starch liquefaction[11]. Soy-flour extracts were kept for 1–4 h with various concentrations of NEMI and their saccharifying and liquefying actions determined. Reduction in formation of reducing sugars depended on the concentration of NEMI in the mixture with soy-flour extract and on the length of incubation. Enzyme inactivation was consistent but small, and even incubation of equal volumes of a 10 per cent soy-flour extract and a saturated solution of NEMI resulted in a decrease of only about 25 per cent in the level of reducing sugars formed. The effects of different concentrations of NEMI and variations in incubation time with the —SH blocking reagent on starch liquefaction by soy-flour extracts are shown in Fig. 1.

Incubation of ten α-amylase preparations[12], at levels comparable in their liquefying action to soy-flour extracts,

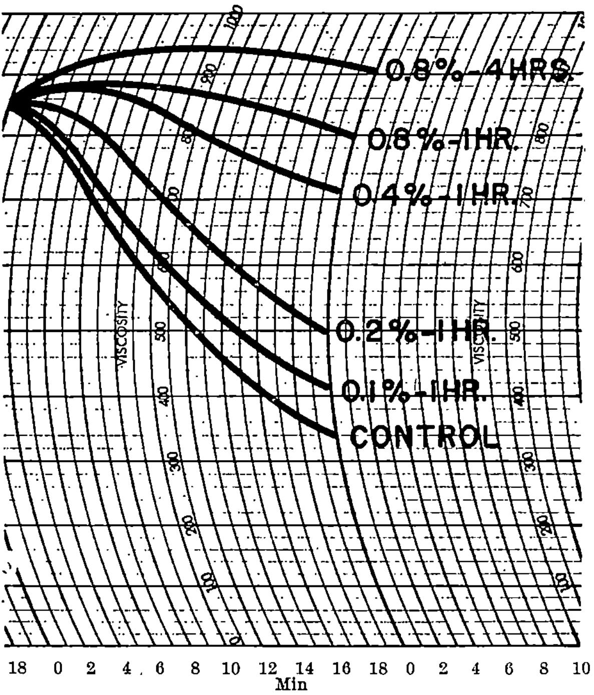

Fig. 1. Liquefaction of pre-gelatinized waxy maize starch by soy-flour extracts incubated with various concentrations of NEMI for 1–4 h

with 0·8 per cent solutions of NEMI for 1 h had no effect on the starch liquefying action of α-amylase from wheat or barley malt, fungi, bacteria, or pancreas. The results obtained confirm the absence of free —SH groups essential for enzymatic activity in cereals, micro-organisms, or pancreas. With regard to the starch-liquefying enzyme in soy-beans two possibilities seem to exist: (*a*) the starch-liquefying enzyme has free —SH groups in the active centre; (*b*) starch liquefaction by soy-flour extracts is the result of an enzyme other than the α-amylase type.

Absorption Spectrum of the Crystal of D-Amino-acid Oxidase Michaelis Complex

Under anaerobic conditions, we crystallized an intermediate complex of enzymatic reaction of D-amino-acid oxidase and a substrate, D-alanine[1,2]. Electron spin resonance examination demonstrated that free radicals are concentrated in the crystal[3]. The crystal was purple under anaerobic conditions, but on aeration it changes to yellow, accompanied by its conversion to equimoles of the oxidized holo-enzyme and the reaction product pyruvate. From these results, we considered that this crystal is an intermediate complex which was composed of equimolar amounts of the semiquinoid form of the holo-enzyme and the partially modified substrate; thus we designated this intermediate as Michaelis complex.

This communication briefly reports the absorption spectrum of this crystal.

The crystal of D-amino-acid oxidase Michaelis complex was prepared as follows. The oxidase was purified as the enzyme–benzoate complex[4]. Benzoate was driven off from the complex by adding an excess of D-alanine. The enzyme was then precipitated by ammonium sulphate at *p*H 6·1. The precipitate was dissolved in the minimum volume of pyrophosphate buffer (M/60, *p*H 8·3). Its final *p*H became 7·2 and saturation of ammonium sulphate, 0·05.

Then, considering the previous results[2] on the molar ratio of pyruvate to the enzyme in the mother liquid which produced large numbers of crystals, pyruvate was added to the purple-coloured solution so that the molar ratio of pyruvate to the enzyme was 200 :1. The solution was kept at 5° C for more than a week under anaerobic conditions. The purple-coloured crystals (about 150μ × 20μ) were gradually formed as shown in Fig. 1. The shape of the crystals is hexagonal prism. They are far larger than the crystal in the previous report[1,2].

The crystals thus obtained were placed on a deck glass and sealed with petrolatum and a cover-glass[3]. Under these conditions, the crystal was stable at least for one day at room temperature. The absorption spectrum at visual wave-lengths of the crystal was measured by using an Olympus microspectrophotometer at 20° C. The diameter of the pinhole was 14μ. The measured absorption spectrum of the crystal is shown in curve 1 in Fig. 2. The absorption spectrum of the purple-coloured mother liquid was obtained under anaerobic condition using Beckmann *DU* spectrophotometer, as shown in curve II in Fig. 2. The absorption spectrum of the crystal is similar to that of the mother liquid, and their peaks are equally located at 492 mμ.

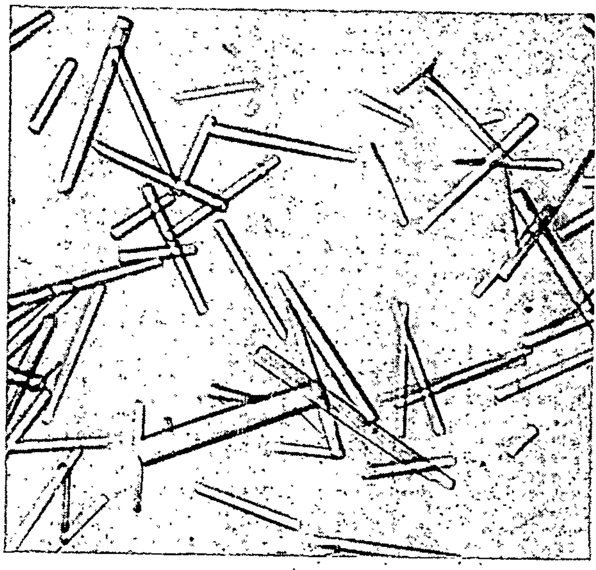

Fig. 1. Crystals of the Michaelis complex of D-amino-acid oxidase (× 200)

They are quite different from both the absorption spectrum of the holo-enzyme crystal (curve III) and that of the holo-enzyme solution (curve IV)[5].

Concerning the absorption spectrum of the semiquinoid form of flavin enzyme, Beinert[6,7] has already reported the transient appearance of a broad absorption band

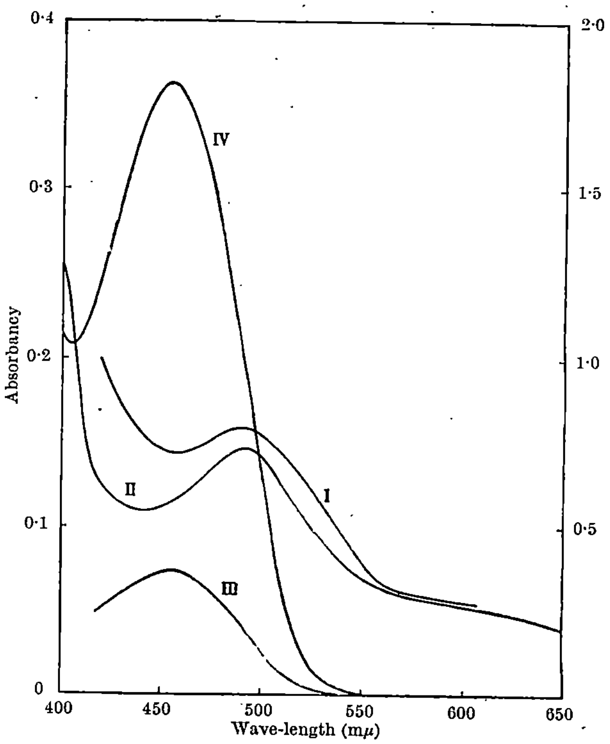

Fig. 2. Absorption spectrum of the Michaelis complex of D-amino-acid oxidase. Curve I, the crystal of the Michaelis complex; curve II, the mother liquid of the Michaelis complex crystal (the enzyme concentration, $1 \cdot 64 \times 10^{-4}$ M); curve III, the crystal of the holo-enzyme; curve IV, the holo-enzyme solution ($1 \cdot 64 \times 10^{-4}$ M in pyrophosphate buffer, *p*H 8·3). The left scale of the ordinate is for curves I and III, and the right for curves II and IV

with its maximum at 565 mμ accompanying the free radical formation for a number of flavin enzymes. Ehrenberg and Ludwig[8] reported the shift of the maximum peak of the old yellow enzyme about 10 mμ toward longer wavelengths (465–475 mμ) accompanying free radical formation.

The difference between the result reported here and those reported by other workers may be attributed to the difference between the enzyme samples or some other reason.

Metabolism of 2,4-Dichlorophenoxyacetic Acid ('2,4-D') by *Aspergillus niger* van Tiegh

Earlier papers dealing with the microbial degradation of 2,4-dichlorophenoxyacetic acid (2,4-D) have indicated that fission may be the ultimate fate of the aromatic ring. Thus Rogoff and Reid[1] detected an almost quantitative production of chloride ion by an organism belonging to the genus *Corynebacterium*, isolated from soil, while Fernley and Evans[2] obtained α-chloromuconic acid as a metabolite using a soil *Pseudomonas* sp., although under certain conditions the latter workers found 2,4-dichlorophenol to be the main product.

By contrast, previous investigations of the metabolism of aryloxyacetic acids by fungi[3-5] have shown that the most notable feature was the predominance of apparently non-specific nuclear hydroxylation, without ring fission. The metabolism of 2,4-dichlorophenoxyacetic acid, using a replacement culture technique with *Aspergillus niger*, has proved different, however, in that not all vacant ring sites are hydroxylated. The major metabolite has been identified as 2,4-dichloro-5-hydroxyphenoxyacetic acid, but two very minor metabolites have been shown to be non-identical with the corresponding 3- or 6-hydroxy acids, the production of which might have been expected in the light of earlier work[4]. These compounds have been separated with some difficulty by partition chromatography using silica gel as the supporting medium for the stationary aqueous phase which was buffered to *p*H 10, the mobile phase being 50 per cent saturated aqueous chloroform/*n*-butanol (60 : 40).

One compound has now been identified by comparison of infra-red absorption spectra and mixed m.p. as the hitherto unknown 2,5-dichloro-4-hydroxyphenoxyacetic acid, an authentic specimen of which was prepared from 2,5-dichlorohydroquinone. The formation of this hydroxy acid from 2,4-D is novel in that it involves not only hydroxyl-chlorine replacement (as was found with 2-chlorophenoxyacetic acid[4]) but also a chlorine shift. This is reminiscent of the formation of homogentisic acid from tyrosine by *A. niger* and various *Penicillium* sp.[6], though in that case it is likely that the side-chain migrates.

2,5-Dichloro-4-hydroxyphenoxyacetic acid is also the sole acidic metabolite produced by *A. niger* from 2,5-dichlorophenoxyacetic acid, but careful scrutiny of the 2,4-dichlorophenol used to prepare the 2,4-D for use in metabolism investigations has not revealed any 2,5-dichlorophenol impurity. Moreover, 2,4-D recovered from the silica-gel column separation, when re-used in the replacement culture technique, resulted in further production of 2,5-dichloro-4-hydroxyphenoxyacetic acid. Final proof of the genesis of 2,5-dichloro-4-hydroxyphenoxyacetic acid was provided by the use of 2,4-D labelled with carbon-14 in the carboxyl group. Metabolism of this acid by *A. niger* gave a radioactive chromatographic spot with the same R_F value.

Thus the bona fide production of 2,5-dichloro-4-hydroxyphenoxyacetic acid from 2,4-D seems certain and the question remains whether its formation is in any way involved in the mechanism of formation of the major metabolite. This appears to be unlikely in view of the fact that no corresponding 4-hydroxy compound is formed in the metabolism of 4-chloro-2-methylphenoxyacetic acid ('MCPA') by *A. niger*, where the previously unknown 4-chloro-5-hydroxy-2-methylphenoxyacetic acid has been identified as the major metabolite.

Utilization of Labelled 'Myleran' for the Determination of the Size of DNA Molecules in Cells

The mutagenic action of the electrophilic alkylating agents has been attributed to many different causes. For Alexander and Stacey[1], the alkylation of the DNA phosphates could be sufficient to induce mutations; but these could also be the consequence of the hydrolysis of the very unstable triester phosphate formed, with rupture of the macromolecule followed by large deletions. Lawley and Brookes[2] have postulated that the 7-alkylation of guanine makes this base couple with thymine instead of cytosine and so is responsible for transitions. But the alkylation of the guanine and adenine residues can also be followed by the loss of the alkylated base[3]: this depurination might act in two ways: the hole left gives the opportunity for transitions, transversions or nucleotide deletions when the DNA replicates, or the DNA sugar-phosphate 'backbone' can break with loss of a part of the chain. All these chemical mechanisms damage only one helix of the DNA molecule exposed to the mono- or bi-functional alkylating drug and the mutation ought to appear only in one half of the genomes of the following generations.

Bridge formation between the two helices by a bifunctional alkylating agent would prevent the DNA replication and lead to the deletion of the cross-linked macromolecule which will have no descent in any genome of the following generations[4]. Besides this qualitative difference, mutation following bridge formation must be quantitatively the most important for bifunctional alkylating agents because the target for the drug is then the whole DNA molecule carrying the competent gene instead of a few sensitive triplets inside this gene.

In a previous publication[4], we tried to evaluate the size of a DNA molecule carrying a known genetic locus by the use of a bifunctional alkylating reagent labelled in its alkyl moiety. Cells of *Chlamydomonas eugametos* Moewus, sex minus, haploid and spontaneously resistant to streptomycin, were treated with 'Myleran' (1,4-dimethanesulphonyloxybutane) labelled with tritium in the butanediol moiety and a correlation was found between the frequency of cells becoming sensitive to streptomycin and the radioactivity of the isolated DNA. Starting from the hypothesis mentioned earlier that, when the mutation reaches all the cells issued from the treated one, the chemical damage must be a cross-linking between the complementary helices of the DNA molecule, and, taking into account the fraction of alkyl groups attached on the DNA which is utilized for cross-linkings, it must be possible to calculate the size of the DNA molecule carrying the competent locus. In the case of *Chlamydomonas eugametos* and the resistance to streptomycin, we tentatively evaluated for the DNA molecule specifically concerned a size of about 3,000,000 A.M.U.; this figure was only provisional in view of the several rather arbitrary corrections introduced in the arithmetics and that must be checked.

The reliability of the labelled 'Myleran' method for the estimation of the weight of an *in situ* DNA molecule biologically characterized depends on two things: (*a*) the stability of the alkyl groups bound to the DNA; (*b*) the knowledge of the percentage of bound alkyl groups forming bridges between the complementary strands of the macromolecule. The examination of these two problems was the purpose of the work reported hereafter.

Calf thymus DNA and 'Myleran' labelled with tritium in positions 2 and 3 of the butanediol moiety (20 mc./m.mole) were used throughout these experiments which were carried out at 22° C. They were dissolved separately before being put together; the final concentration of 'Myleran' was always 0·1 mg/ml. The radioactivity determinations were performed by liquid scintillation counting after suitable preparation of the sample.

(*A*) In a first set of experiments, the DNA was left for 3 h in contact with the T-'Myleran' before precipitation (addition of solid sodium chloride to bring the concentration to 1 M, then of an equal volume of 95 per cent ethanol). The fibres were washed three times with absolute ethanol and afterwards with anhydrous acetone until this solvent did not extract any more radioactivity. At this stage the alkylated DNA radioactivity was 9,100 d.p.m. mg.

This alkylated DNA was redissolved in water and DNA reprecipitated from aliquots at various time intervals. Fig. 1 shows that there was a sudden drop of the DNA radioactivity followed by a plateau.

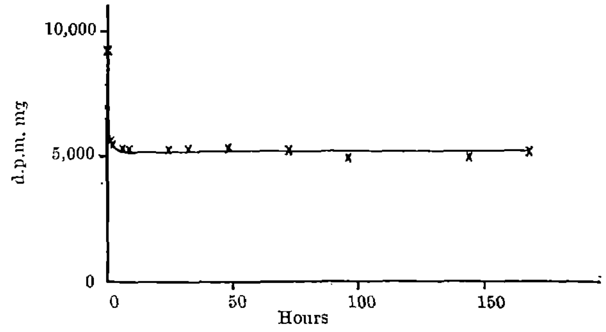

Fig. 1

To understand the meaning of the initial drop, the supernatant was percolated through an 'Amberlite IR-120(H)' column: 80 per cent of the activity came with the effluent and the water washings, while 20 per cent were retained and could be eluted with N ammonium hydroxide. The 20 per cent are thus alkylated bases. The 80 per cent (2,800 d.p.m. mg DNA) are due either to the hydrolysis of alkyl phosphates[5], or to a contamination by unreacted 'Myleran'. It is noteworthy that, when the DNA is precipitated from the solution immediately after it has been put in contact with the T-'Myleran', the activity bound to the DNA is precisely 2,800 d.p.m. mg.

Of the total of 9,100 d.p.m., we see that only 700 d.p.m. was lost as hydrolysed alkylated bases. Of course, there could also be some depurination during the 3 h contact between DNA and T-'Myleran': but the large radioactivity of the unreacted 'Myleran' prevents the detection of alkylated bases in the supernatant after precipitation of the DNA.

Most important from our point of view is the fact that, after the initial drop, the specific activity of the alkylated DNA is completely stable, around 5,000 d/min mg in our experiment. At this stage, the DNA can be dissolved and precipitated many times in succession without change of the specific activity: this proves that the precipitation procedure does not differentiate between alkylated and non-alkylated DNA.

This alkylated DNA of stable specific activity was hydrolysed for 30 min in 98 per cent formic acid at 175° C[6] and the hydrolysate evaporated to dryness under vacuum. The residue was dissolved in N hydrochloric acid and filtered. After substitution of water for N hydrochloric acid, the solution was passed through a column of 'Amberlite IR-120(H)' and the ion-exchanger washed with water; the effluent contained 880 d.p.m. (per mg hydrolysed DNA) which was not bound to compounds absorbing at 260 mμ. The column was afterwards eluted with N ammonium hydroxide which carried away the weak bases and 3,500 d.p.m. per mg DNA. This shows that most of the radioactivity firmly bound to the DNA is in alkyl groups attached on the bases of the macromolecule. The base fraction was submitted to a two-dimensional paper chromatography (methanol/ethanol/conc. hydrochloric acid/water (50 : 25 : 6 : 19, by vol.) and n-butanol/conc. ammonium hydroxide/water (86 : 1 : 13, by vol.)): the ultra-violet showed the fluorescent spots of the four bases plus two faint extra ones at the sites given by Brookes and Lawley[7] for the 7-alkyl derivative of guanine ($R_F = 0{\cdot}48$ and 0·15) and the corresponding di-guanyl compound ($R_F = 0{\cdot}26$ and 0·00). Radioactivity was found only at the sites of these two latter spots: respectively 2,950 and 250 d.p.m. (per mg hydrolysed DNA). The conclusion is that the stable radioactivity fixed on DNA after reaction with the T-'Myleran' is mostly in alkylated guanines with about 8 per cent forming bridges between two neighbouring guanine residues.

(*B*) In a second set of experiments, the DNA was left continuously in the presence of the T-'Myleran' in a 0·1 M phosphate buffer solution of pH 6·6. The DNA was precipitated from aliquots at various time-intervals and the fibres carefully washed with anhydrous acetone before the radioactivity determination. The solid line of Fig. 2 shows a continuous but non-linear increase of the radioactivity bound to the DNA. (The radioactivity found at time 0 was taken as a contamination by unreacted 'Myleran' and all the results were corrected accordingly.) In the reaction kinetics, the DNA can be considered in excess since, at the highest point of the curve, there is only one alkyl group per 3,000 nucleotides. On the other hand, the half-life of the 'Myleran', at the same temperature and in the same buffer, was shown to be 132 h, which means that the k_1 constant of the hydrolysis of the di-ester to the mono-ester has a value of $8{\cdot}75 \times 10^{-5}$ min^{-1}. Taking into account only the hydrolysis of the 'Myleran' (and assuming no participation of the mono-ester), the radioactivity (d.p.m.) bound per mg DNA ought to be:

$$x = \frac{k_2}{k_1}(1 - e^{-k_1 t})$$

where $k_2 = 19{\cdot}2$ min^{-1} is read from the initial slope of the solid curve drawn on Fig. 2. The theoretical curve of the 'x' values is depicted by a dashed line on the same graph: it is above the experimental one. The difference might be due, at least in part, to the existence of labile pools of tritium bound to the DNA.

The foregoing results indicate that, after treatment of the DNA with tritiated myleran, several pools of bound tritium are formed: a very labile, which might be alkyl phosphates but the existence of which has not been proved unambiguously (it could be a contamination by unreacted 'Myleran'); a medium labile one of alkyl bases; and, quantitatively most important of all, a stable pool also of alkyl bases. The stably bound tritium can be used

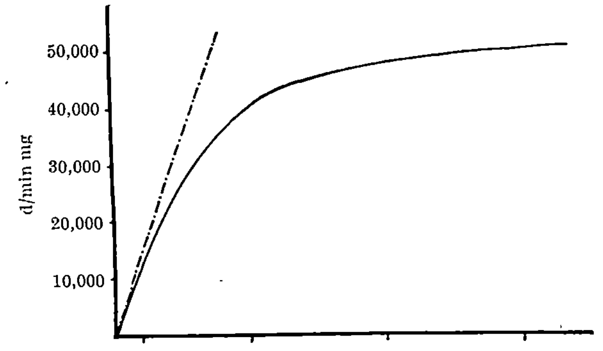

Fig. 2

as an index of the magnitude of the alkylation undergone by the DNA.

The analysis of the stably bound radioactivity has shown that it is mostly in alkyl groups attached to guanine residues with about 8 per cent linking together two guanines. We have no proof that these two guanines belong, in every instance, to the DNA complementary strands. Further work must be done to have the exact ratio between the stably bound alkyl groups and the bridges between the DNA helices. Even without this knowledge, relative molecular weights of *in situ* DNA molecules could be estimated by the 'Myleran' method; the ratio is, however, expected to be influenced by the base composition of the DNA's.

This technique of *in situ* evaluation of the weight of a DNA molecule functionally characterized by the use of a bifunctional alkylating agent has also some bearing on the elaboration of a reasonable model for non-bacterial cell chromosomes. The underlying hypothesis can be borne out only if the chromosomes of such cells are composed of independent DNA molecules glued together by more fragile linkers. On the other hand, the method actually provides a means to detect genetic loci carried by the same DNA molecule and to inquire whether each DNA molecule is an integrated operational unit[8].

Accumulation of Acetoin by Myo-inositol-deficient Yeast

MYO-INOSITOL deficient cultures of *Saccharomyces carlsbergensis* strain 4228 (A.T.C.C. 9080) have been reported to grow both at a diminished rate and in abnormal cellular aggregates[1,2]. A comparison of the composition of deficient and normal cells revealed that myo-inositol deficiency led to an accumulation of glucans in cell walls[2]. This communication discusses another biochemical abnormality in myo-inositol deficiency resulting in the accumulation of enhanced amount of acetoin in *S. carlsbergensis* culture medium deficient in myo-inositol.

Aliquots (1 ml.) of a suspension of washed *S. carlsbergensis* cells (Klett Summerson reading of approximately 100, versus water blank, using No. 66 filter) were used to inoculate litre Erlenmeyer flasks containing 400 ml. of the myo-inositol assay medium of McKibbin[3] modified by deletion of casein hydrolysate and choline. Control flasks contained the foregoing medium supplemented with 5 mg of myo-inositol. The flasks were incubated at 28° C with shaking (New Brunswick gyrotory shaker, 143 oscillation min) and samples of growth medium were removed periodically. When supernatant fluids obtained from centrifuged resting phase cultures were analysed for glucose the myo-inositol-deficient media appeared to contain copper reducing material (by Clinitest, Ames Co., Inc., Elkhart, Ind.) which was not glucose, since it did not react with glucose oxidase test paper (Testape, Eli Lilly and Co., Indianapolis, Ind.). Afterwards, broth obtained from the deficient cultures was distilled *in vacuo* at 40° C and the distillate was shown to reduce alkaline copper solutions and to have an ultra-violet absorption maximum at 275 mμ. On addition of semicarbazide hydrochloride and sodium acetate the absorption maximum at 275 mμ disappeared and a crystalline precipitate with a melting point at 195° C was formed. This corresponds to the reported value of 193°–194° C for acetoin semicarbazone[4]. Elementary analyses were similar to those calculated for acetoin semicarbazone.

	C	H	N
Found	40·3	8·0	29·3
Calculated	41·3	7·6	29·0

Another derivative, the phenylosazone, melted at 234° C, in agreement with that reported for the biacetyl phenylosazone derived from acetoin[4].

Acetoin determinations, using the procedure of Westerfeld[5], provided data (Fig. 1) which showed that deficient cells accumulated approximately 5–8 times more acetoin than normal cells. The relatively high level of acetoin appeared sufficient to account for the previously observed copper reduction.

Acetoin accumulates in the broth during the period of most rapid growth of the deficient cells, and ceases when glucose is no longer present. This is consistent with mechanisms established for acetoin formation, in which the glucose metabolite, pyruvate, is a critical intermediate[6]. Further preliminary results indicate that other materials with reducing properties also accumulate in inositol-

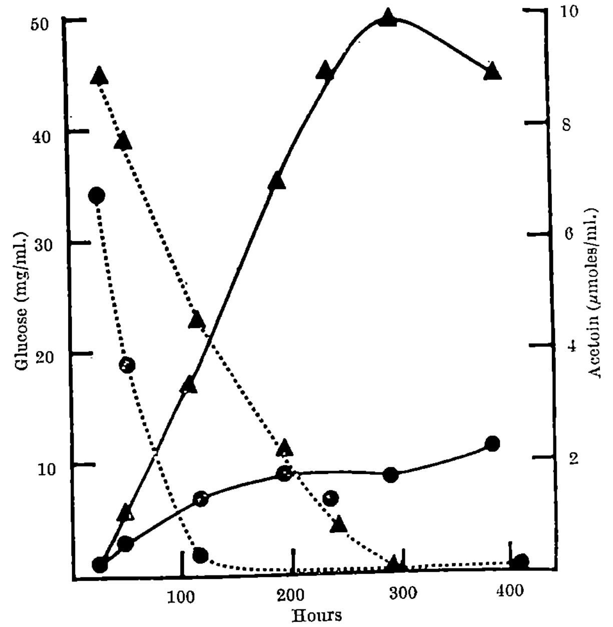

Fig. 1. Utilization of glucose and production of acetoin by *S. carlsbergensis* grown in the presence (●) and absence (▲) of myoinositol. Glucose (– – –) was determined using glucostat reagent (ref. 9), and acetoin (——) was assayed colorimetrically as described in the text

deficient supernatant broths. Analyses for acetaldehyde by the method of Desnuelle and Naudet[7] and by that of Barker and Summerson[8] modified by eliminating prior heat treatment indicate that this acetoin precursor may also accumulate in myo-inositol-deficient media. Paper chromatography of such media also demonstrated the presence of additional non-volatile compounds capable of reducing silver nitrate. The nature of these compounds, their interrelationships, and a connexion with the fundamental lesion or lesions of myo-inositol deficiency are undergoing further investigation in this laboratory. It is not clear whether the accumulation of the compounds described herein is a direct or indirect consequence of myo-inositol deficiency. It is believed that clarification of the nature of these reactions will lead to an understanding of the metabolic role of this vitamin.

The work was supported by research grants from the U.S. National Science Foundation (*GB* 2318) and from the Washington Heart Association. The elementary analyses of acetoin semicarbazone were performed by Chemco Inc., Washington, D.C.

Thermal Changes in the *Nautilus* Shell

IN the shells of recent molluscs, the nacreous conchiolin appears in the electron microscope in the form of lace-like reticulated sheets or perforated leaflets[1,2]. Three patterns of structure (nautiloid, gastropod and pelecypod), differing by the size and the shape of the trabeculæ and by the disposition of the fenestration, have been provisionally recognized in these sheets.

Remnants of conchiolin have also been identified with the electron microscope in the shells of about 100 species of Palæozoic, Mesozoic and Cenozoic molluscs (refs. 3 and 4, and unpublished observations), some of them having retained the characteristic proteins of the nacreous conchiolin[5]. Well-preserved sheets of nacreous conchiolin were detected, for example, in cephalopodan shells buried in the Buckhorn asphaltic sandstones of Oklahoma[3]. In shells from other horizons, these remains were mostly modified in their structure. Examination of more than three thousand micrographs revealed that, in many fossil tests, the alterations in the conchiolin pattern consisted of flattening, thinning, shrinkage and coalescence of the trabeculæ, and conversely bloatings into vesicles of the protuberances protruding on these trabeculæ. In a more advanced stage of degradation, fragmentation of the trabeculæ resulted in formation of lenticular or rounded pebble-shaped segments or corpuscles of various sizes, generally clustered on the supporting film, and sometimes (as in an Oligocene *Aturia*[3]) appearing as riddled by tiny sieve-pits.

When the characteristic conchiolin pattern is not found in a sample, the nature of these structures is uncertain and confusion is possible with foreign contaminating matter (for example, fragments of bacteria, algae, fungi or sponges). However, several criteria, among which positive biuret tests, detection of transitional aspects between trabeculæ and pebbles in limited areas of well-preserved reticulated sheets, suggest that these structures are actually altered conchiolin.

Additional evidence for identification of these structures to conchiolin is furnished by the following observations. In order to appreciate the part played by temperature, one of the chief factors involved in diagenesis, in development of these structural alterations of conchiolin, fragments of mother-of-pearl from *Nautilus macromphalus* Sowerby and *Nautilus pompilius* Lamarck were exposed for 5 h in a dry oven to temperatures ranging from 150°–700° C. Other nacreous fragments were kept in the oven at 150° C for 11, 13 and 19 days. The results are summarized here.

Effects of temperature on preservation of organic constituents in shells (amino-acids) have already been examined in accelerated ageing tests by Abelson[6].

Mineral components. Mother-of-pearl is a hard substance, which breaks without cleavage, except on the outer margin of the fragments. Unpolished fragments are faintly iridescent, with pale pink-greenish hues. The effects of dry heat on that material consist of progressive increase in brittleness and easier cleavage into many thin flakes (200° C and above). At 500° C and above, the nacreous matter is transformed into a snow-white powdery substance.

A slight burnishing of the iridescence appears at 150° C and develops with elevation of temperature. Between 200° C and 300° C the cleaved flakes exhibit intense metallic colours and resemble closely the strongly variegated nacreous remnants of many Cretaceous cephalopodan tests (for example, Senonian *Eutrephoceras*, or tests from Ripley and Coon Creek Formations). Protracted exposure to 150° C produced the same changes. Iridescence disappears above 400° C.

X-ray powder diffraction analysis revealed the preservation of the original aragonite in the 150°–300° C samples, transformation into calcite in the 400° C and 500° C samples and into calcium hydroxide in the 600° C and 700° C samples, with traces of calcite.

Organic components. The organic structures were examined on samples decalcified with a chelating agent (EDTAA disodium salt: 'Titriplex III' Merck). The samples heated in the range 150°–500° C dissolved rapidly, with intense emission of bubbles. At 200° C and above, a strong smell of petrol was noticeable, as in all the fossil samples treated in the same way. In the samples composed of calcium hydroxide heated to 600° C and 700° C, the chelating decalcifier produced a considerable effervescence for a short time. The mineral substance remained then inert as a white mud. Only a small portion of this mud could be dissolved in a 25 per cent solution of hydrochloric acid. It recrystallized soon afterwards.

The conchiolin residues appeared as transparent shreds (in the 150° C samples heated for 5 h: as in the untreated material), as mahogany-brown (in the 200°–300° C samples) and brown-black particles (400° C and above samples). The two last-mentioned aspects are constant findings in the fossil shell material.

In all the samples, including those heated to 700° C, the biuret test showed under the conventional microscope pink and violet flakes corresponding to shreds of nacreous conchiolin.

Electron microscopy. The residues of decalcification were mounted on usual supporting films of 'Formvar', shadow-cast with palladium and examined with an R.C.A. electron microscope. The results are based on more than 400 micrographic records. Exposure to 150° C (for 5 h, 11, 13 and 19 days), to 200° C and to 225° C for 5 h altered only slightly the appearance of the reticulated sheets of nacreous conchiolin, consisting of sturdy trabeculæ with scattered protuberances, separated by an irregularly broad fenestration, characters of the nautiloid pattern (Fig. 1). In the 225° C sample, pebble-shaped swellings developed on the trabeculæ were the first signs of disintegration.

Fig. 1. *Nautilus pompilius* Lamarck. Mother-of-pearl from the shell wall, heated before decalcification to 150° C for 5 h. Fragments of a reticulated sheet of conchiolin are shown (nautiloid pattern) (× *c.* 14,000)

Fig. 2. *Eoasianites hyattianus* (Girty) (Ammonoidea), Pennsylvanian, Buckhorn Asphalt, Sulphur, Oklahoma. Decalcified mother-of-pearl from an altered portion of the shell wall. Conchiolin remnants composed mostly of clustered, rounded bodies of various sizes (× *c.* 14,000)

Fig. 3. *Nautilus pompilius* Lamarck. Mother-of-pearl from the shell wall, heated before demineralization to 600° C for 5 h. Remains of reticulated sheets of conchiolin consist of rounded bodies of various sizes (× *c.* 14,000)

In the three figures, the shadows, directed upwards, behind the rounded bodies, appear as white triangles

Higher temperatures induced progressively disappearance of the nautiloid pattern by dislocation of the trabeculæ into rounded pebble-shaped fragments clustered at random by desiccation on the supporting films. These alterations, which precede transformation into calcite of the aragonite embedding the sheets, resemble those consistently recorded in the fossil samples of Palæozoic and Mesozoic mollusc shells (Figs. 2 and 3). They reflect probably morphological effects of degradation in some of the constituent proteins of the shell.

I thank Prof. William M. Furnish and Prof. B. F. Glenister, who supplied a fragment from *Eoasianites*, Mr. G. Casier, who performed the heatings of the material, and Mr. J. Grandjean, who recorded and analysed the X-ray diffraction patterns.

Biosynthesis of Ethylene

It is the purpose of the present communication to describe some further results with carbon-14 precursors of ethylene, and to reconcile the pattern which emerges in these investigations using McIntosh apple tissue sections with that of the fungal system, *Penicillium digitatum*. The procedures have been described previously[1–3], and their reliability for measuring ^{14}C-ethylene and carbon dioxide commented on[3]; they were altered only in the use of a Cary–Tolbert ionization chamber in place of a Bernstein–Ballentine tube for measuring radiation. In the course of these experiments it was noted that alcohol vapour interferes with the assay for ethylene by dissolving in mercuric perchlorate absorbent where a slow acid-catalysed dehydration occurs. For example, when 10 µl. liquid ethanol was added to 20 ml. of mercuric perchlorate reagent, ethylene appeared at a linear rate for at least 6 h, by which time 0·02 per cent of the alcohol had been converted to olefine. Previously, Young *et al.*[9] reported that ethanol was not measured by the mercuric perchlorate manometric procedure, but they apparently took no account of the duration of contact between alcohol and perchlorate, and it should be noted that gas chromatography detects much smaller quantities of vapour than does manometry. In the work recorded here it was determined that a discernible error could occur only if at the end of a collection period in excess of 1 µc. of ^{14}C-ethanol had been formed in the tissue. In experiments with fumarate and acetate this would require that labelled ethanol form at approximately the same rate as $^{14}CO_2$, and with other compounds ethanol production would greatly have to exceed $^{14}CO_2$ evolution. Clearly, under the conditions of the assay, the results are not influenced by this factor except when ^{14}C-ethanol itself was administered to the tissue (Table 1), in which case the apparent transfer of label to ethylene must be dismissed as an artefact.

Table 1. CONVERSION OF CARBON-14 SUBSTRATES TO ETHYLENE AND CARBON DIOXIDE IN APPLE TISSUE

		Specific activity (d.p.m./µg C)*

* Per 100 µc. administered ^{14}C of S.A. = 2 mc./mM.
† Times are intervals after the tissue was soaked for 60 min in the isotopic solution.
‡ $^{14}CO_2$ was present only during the 0–80′ collection period.

Previously, the conversion of the individual carbons of glucose to ethylene was evaluated in both *P. digitatum*[8] and McIntosh apples[3] with closely similar results. The relative ease of conversion to ethylene of carbon(s) 6 : 1 : 2 : (3 + 4 + 5) was 3·2 : 1·0 : 1·1 : 2·5 in apples and 2·4 : 1·3 : 1·0 : 1·9 in the fungus. To the extent that the hexose monophosphate pathway (HMP) functions in both tissues, triose will form preferentially from carbons 4–6 of glucose, and if ethylene arises from triose the 6-C of glucose should yield labelled ethylene more readily than the 1-C. In both tissues a significant contribution of the HMP pathway has been reported[3,7], and assuming ethylene to form from triose, the contribution to ethylene of the 6-C of glucose relative to the 1-C is quantitatively consistent with the respiratory data for apples[3] and would be so for *P. digitatum* if the 23 per cent estimate of the HMP pathway in that tissue[7] is a slight underestimate. Significantly, Katz and Wood[5] caution that the HMP calculation for *P. digitatum* may be in error since it fails to take into account carbon recycling and incomplete oxidation. Because of the aforementioned considerations, the 2-C of glucose cannot be equated to the 5-C as suggested by Wang *et al.*[8], but rather the ratio of ease of conversion to ethylene of the 1-C relative to the 6-C might be expected to be similar to that of the 2-C relative to the 5-C. If this were true, it can be calculated that the 3,4-C's of glucose do not contribute to ethylene formation in either tissue.

Carbon recycling by the HMP pathway would transfer label from the 2-C to the 1-C position of glucose-6-phosphate, but this cannot quantitatively account for the participation of the 2-C in ethylene synthesis because even at equilibrium in a tissue respiring entirely by the HMP pathway, after application of the 2-^{14}C-glucose the specific activity of the 1-C of glucose-6-phosphate would be only 1/3 that of the 2-C (ref. 5). Similarly, although in *P. digitatum* a significant conversion of the carboxyl carbon of acetate to the amino-carbon of aspartate occurs[6], this mechanism is not sufficient to explain the nearly equal yields in ethylene from 1- and 2-^{14}C-glucose. In apples, results with 2-^{14}C-pyruvate, 1-^{14}C-acetate, 1,4-^{14}C-fumarate and $^{14}CO_2$ (Table 1) emphasize that the 2-C of triose may be converted to ethylene by oxidative decarboxylation of pyruvate and metabolism of the resultant acetate in the Krebs cycle. It should be noted that even with 1-^{14}C-acetate, at no time did the $^{14}CO_2$ content surrounding the tissue rise above a level that could account for more than 6 per cent of the activity in ethylene, as judged by experiments with applied $^{14}CO_2$ (Table 1). Likewise, with *P. digitatum*, Gibson and Crane[4] reported that in 3 h experiments a significant conversion of 2-^{14}C pyruvate to ethylene occurred. Since during the first 80 min after isotope is administered to apples, carbons 1 and 2 of pyruvate are equally effective in forming ethylene, as are carbons 1 and 2 of acetate and 1,4 versus 2,3 of fumarate, it is likely that the 2,3-C's of triose are converted to ethylene as a unit, via acetate and Krebs cycle intermediates. This interpretation cannot be reconciled with the suggestion of Wang *et al.*[8] that ethylene forms by a double decarboxylation of fumaric acid, for such a mechanism demands that the yield from the carboxyl carbon(s) of fumarate and acetate be low, initially, perhaps increasing with time. There is no discrepancy between the behaviour of McIntosh apples and the *P. digitatum* culture used by Wang *et al.*, for as the duration of the experiments with apples is extended to 200 min (Table 1) the data resemble more and more the six-day cumulative results with the mould[8]; namely, carbon positions metabolically related to the methylene carbons of fumarate are preferentially used for ethylene synthesis. This phenomenon previously was noted[1] when 1-^{14}C-acetate and U-^{14}C-sucrose were found to be almost equally effective in forming labelled ethylene during 22 h after injection into the ovary of a whole apple, whereas in the next 36 h the specific activity of ethylene declined significantly in the acetate experiment, and increased markedly with sucrose. A major result of prolonging the duration of investigations of this type is to invite complication by isotope redistribution, and the different patterns obtained in short- and long-term experiments with organic acids or related compounds may be due to the fact that a carboxyl label is readily lost as carbon dioxide, whereas the 2-C of acetate and 2,3-C of fumarate tend to be recycled through the Krebs cycle and retained. For example, in experiments with apple tissue slices, about 45 per cent of the label applied as 1-^{14}C-acetate, but only 9 per cent of the activity fed as 2-^{14}C-acetate, appeared in carbon dioxide within 200 min. In the case of fumarate, 16 and 4 per cent of the administered activity was recovered as $^{14}CO_2$, respectively, from the 1,4- versus 2,3-C isotopes in the same period of time. When it is considered that only about 55 per cent of the ^{14}C-acetate and 30 per cent of the labelled fumarate entered the slices, the results indicate that depletion of the carboxyl carbon within the tissue limited its conversion to ethylene in experiments lasting several hours. Although figures are not available for *P. digitatum* under conditions exactly resembling those in which ethylene was assayed, it has been reported that the cells of *P. digitatum* retain the 2-C of acetate to about twice the extent of the 1-C (ref. 6).

With apples, the maximum specific activity thus far reported for ethylene amounts to only 0·3 per cent of that in the applied isotope (2,3-^{14}C fumarate), and for *P. digitatum* the highest average value is only 0·1 per cent (3,4-^{14}C glutamate). In apples it is certain that the low activity in ethylene cannot be explained by isotope dilution of the applied substance by a tissue pool because the carbon dioxide produced during 200 min with ^{14}C-acetate has a specific activity of between 13–20 per cent of that theoretically possible, and with 1,4-^{14}C-fumarate the value was 4–5 per cent. In fact, with all isotopes except glucose, the carbon dioxide acquired a significantly higher specific activity than ethylene, which suggests that although ethylene formation is related to the metabolism of Krebs-cycle acids as suggested by Wang *et al.*[8], still it is presumptuous to conclude that the relationship is very direct.

Antioxidants isolated from Fermented Soybeans (Tempeh)

In an examination of the nutritional value of tempeh, which is prepared by the action of *Rhizopus oryzae* on boiled soybeans, rats fed tempeh showed better growth and greater resistance of red blood cells to *in vitro* dialuric acid-induced hæmolysis than rats fed plain boiled soybeans[1]. Hæmolysis of red blood cells induced by dialuric acid or by appropriate low concentration of hydrogen peroxide indicates in general a deficiency of vitamin E as a biologically highly effective antioxidant[2,3]. The comparative findings between boiled and boiled-fermented (tempeh) soybeans seems to support the preliminary conclusion that antioxidants were either formed *de novo* or liberated during fermentation through fungal activity from complex, originally inactive compounds, present in unfermented soybeans.

Paper chromatographic analysis by the procedure of Russell Eggitt and Ward[4] of alcohol and ether extracts of dried powdered tempeh indicated the presence of a substance at R_F 0·92 giving a positive ferric chloride reaction and Emmerie–Engel test. The spot did not correspond to α-tocopherol, or to *F* 84, isolated from yeast[5] and identified as 2-(6-hydroxy-2-methoxy-3,4-methylene-dioxyphenyl)-benzofuran[6]. An eluate of the section of the paper corresponding to R_F 0·92 prevented the hæmolysis of red blood cells of vitamin E-deficient rats with dialuric acid[7].

The *in vitro* test of hæmolysis-preventing activities of samples was carried out according to the procedure of Rose and György[2] as adapted by Forbes and György[8]. The activity was expressed as the number of 'hæmolysis prevention' units per mg; a unit was defined as weight

of substance preventing hæmolysis as well as 0·2 μg of α-tocopherol.

An extract of control soybeans had very low activity. The activity approached that of tempeh after hydrolysis with hydrochloric acid.

After many attempts to isolate the active antioxidant from tempeh, three kinds of anti-hæmolytic substances were isolated in crystalline forms. For their isolation the following procedure was used[7]: (1) Powdered tempeh was extracted with 95 per cent ethanol and the alcohol extract was concentrated to syrupy consistence. (2) The syrupy residue was extracted with 50 per cent ethanol and the solvent was evaporated off. (3) The condensed oily material was extracted with ether and the ether of the extract was evaporated. (4) The residue was treated with 25 per cent ethanol. Crystals of m.p. 323° and 298° were obtained from 25 per cent alcohol-insoluble fraction. (5) The 25 per cent alcohol soluble part was fractionated by polyamide column chromatography as shown in Fig. 1. Peak 5 was shown by paper chromatography to contain daidzein and an unknown substance, called 'Factor 2'. (6) Factor 2 was separated from daidzein in a large-scale paper chromatographical experiment using butanol/ethanol/borate (1 : 1 : 1), and extracted from the paper with alkaline water, acidified, and transferred to ether. From the ether fraction the active substance was crystallized. (7) The crystals of m.p. 320° (decomp.) were obtained by recrystallization from dioxane. The yield was only 20 mg in a pure form out of 5 kg dried tempeh.

Crystals of m.p. 323° and 298° were respectively identified as daidzein (7,4′-dihydroxyisoflavone) and genistein (5,7,4′-trihydroxyisoflavone) by identity of melting points, elementary analysis, ultra-violet spectra, R_F value, colour reactions, and hæmolysis *in vitro* test with those of known specimens. Hæmolysis preventing activity of Factor 2 was much higher than that of daidzein and genistein. The activities of these substances are shown in Table 1 together with other properties.

From infra-red and ultra-violet spectra, colour reaction (ferric chloride and Emmerie–Engel), and melting point, Factor 2 was presumed to be the same substance as 6,7,4′-trihydroxyisoflavone, prepared originally from afromosin, which is present in *Afromosia elata*[9,10]. This working hypothesis was conclusively proved to be correct by direct comparison of pure 6,7,4′-trihydroxyisoflavone with pure Factor 2 (Table 2 and Fig. 2). (We thank Dr. T. B. H. McMurry for the specimen of 6,7,4′-trihydroxyisoflavone and Dr. K. Fukui, Dr. S. Shibata and Dr. N. Inoue for their advice.)

Daidzein and genistein are the aglucones of the known glucosides, daidzin and genistin. Enzymatic hydrolysis of the glucosides through the action of *Rhizopus oryzae* has been proved by the use of aqueous extract of the fungus on boiled extracts of unfermented soybeans (unpublished observations). The presence of 6,7,4′-trihydroxyisoflavone in natural products has not yet been demonstrated. Our investigations have to be extended to the demonstration of 6,7,4′-trihydroxyisoflavone in unfermented soybeans. In the absence of this information, the possibility of the *de novo* synthesis of 6,7,4′-trihydroxyisoflavone through fungal action cannot be excluded.

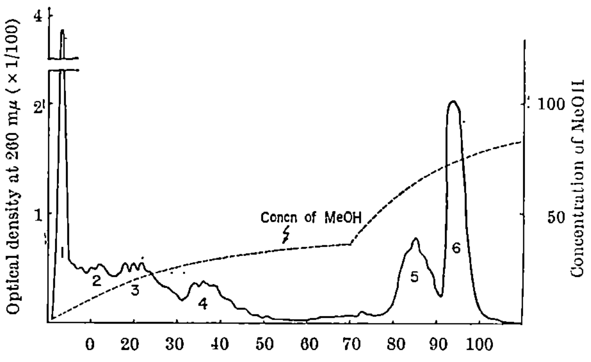

Fig. 1. Polyamide column chromatography of tempeh extract (gradient elution with water–methanol)

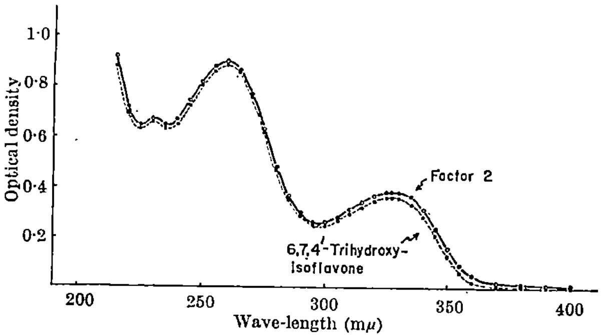

Fig. 2. Ultra-violet spectra of Factor 2 and 6,7,4'-trihydroxyisoflavone (10 μg/ml. in 99 per cent ethanol)

However, the high antioxidant activity of hydrochloric acid-hydrolysed extracts prepared from unfermented soybeans being of the same order as that of extracts obtained from fermented soybeans favours the conclusion that the highly active 6,7,4'-trihydroxyisoflavone is a normal constituent of soybeans.

The antioxidants liberated in tempeh act probably through their protection and preservation of the biologically eminently effective vitamin E in soybeans and not by direct biological action. When larger amounts of 6,7,4'-trihydroxyisoflavone become available, its antioxidant effect in vitamin E-deficient animals should be investigated.

PHYSIOLOGY

Lability of the Action Potential and the Recovery Cycle from Isolated Motor Axons of the Crab, *Carcinus*

The action potential evoked from an artificially produced excitable node of isolated crab axon membrane[1] shows similar changes to those described for the isolated toad node[2], when currents are applied during the action potential itself. The rising phase of the action potential can be modified only by very considerable anodal currents (some 40 times rheobase), but the repolarization phase shows changes when weak currents of either polarity are applied (Fig. 1). Repolarization is delayed by cathodal current and is hastened by anodal current, when these are applied during the falling phase of the action potential. The divergence of the voltage profile of repolarization, produced by a constant current pulse of either polarity, is greater the later it is applied, as would be expected from the form of the change in membrane resistance that accompanies the voltage change of the action potential. The changes in the rate of repolarization are proportional to the strength of the applied current and its duration, so that complete repolarization can be achieved with strong anodal current, that is, the later phase of the action potential can be abolished.

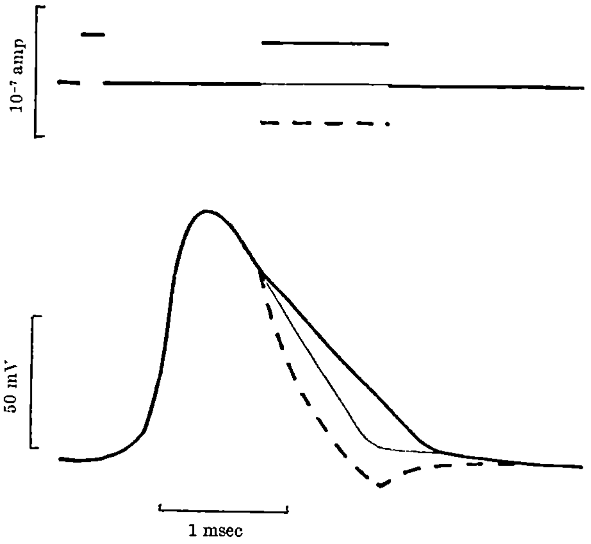

Fig. 1. Tracings from original records illustrating the modification of the form of the action potential when anodal current (dashed line), and cathodal current (solid line) are applied during the repolarization phase. The normal course of repolarization is shown by the fine solid line. Action potentials are evoked from an artificial node of excitable membrane, crab motor axon, 17° C

The form of the recovery of the spike generating mechanisms following an action potential is also modified by currents applied during the repolarization phase, as is shown by the recovery of spike amplitude, threshold current and potential threshold. An action potential shortened by anodal current is followed by a more rapid recovery, while one prolonged by cathodal current is

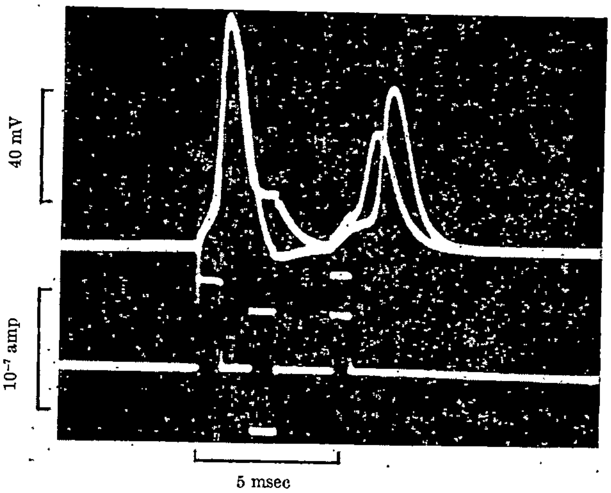

Fig. 2. Two superimposed records comparing the effects on recovery following an action potential, when that action potential has been shortened by anodal current or lengthened by cathodal current. The recovery is more rapid following treatment with anodal current, as is seen from the weaker threshold current, the greater spike amplitude, and the lower threshold potential. Artificial node of a crab motor axon, 17° C

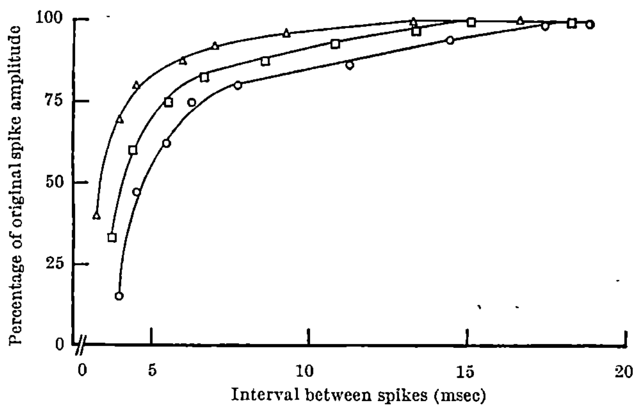

Fig. 3. The normal recovery cycle (□) is shorter in duration following treatment of the action potential with anodal current during repolarization (△), while prolongation follows treatment with cathodal current (○). Isolated crab motor axon, 17° C

followed by a slower recovery (Figs. 2 and 3), during which the spike amplitude, the critical level of depolarization for the spike, and the current threshold show parallel changes.

These findings are of obvious importance when the form of the response of these axons to maintained depolarization is considered. It has long been known that the form and duration of the recovery cycle cannot alone account for the nature of the response to maintained cathodal current in crab axons[3], if the recovery cycle remains unchanged throughout the response. Fuortes and Mantegazzini[4] on the eccentric cells of *Limulus* eye, and personal observations on crab axons, have shown that it is necessary to consider that sustained depolarization has an additional depressant effect on excitability, since higher discharge frequencies are obtained by stimulation with trains of short current pulses than are elicited by a maintained current of the same current strength, beyond a certain frequency. This depressant action of sustained depolarization can be equated with the prolongation of the recovery cycle which is found when cathodal currents are applied during the action potential.

The underlying changes associated with the modification of the action potential by anodal currents has been considered by Huxley[5]. He has shown that the Hodgkin–Huxley equations account for this behaviour since the sodium conductance is reversible during the action potential. The modification of the action potential in crab axons by applied currents can be interpreted similarly; a reversibility of inactivation and/or the potassium conductance can also be inferred from the changes in the recovery cycle.

Biliary Excretion of Cæruloplasmin Copper

The importance of the mechanism by which normal subjects maintain zero balance of copper is seen in patients with Wilson's disease who, lacking it, accumulate copper to the point of toxicity. In these patients, the association of chronic copper toxicity and life-long deficiency of cæruloplasmin has aroused considerable speculation about a possible role of this copper-protein in the control of either absorption or excretion of copper[1]. Since earlier studies failed to indicate an effect of circulating cæruloplasmin on the absorption of copper[2], our attention has recently been directed on the alternative possibility that cæruloplasmin is involved in the excretory pathway of copper. Bile is a major route for the excretion of heavy metals; the question arose therefore whether cæruloplasmin copper passes directly into bile, as suggested by Jeunet, Richterich and Aebi[3]. This was answered by intravenously injecting cæruloplasmin labelled with copper-64 into rabbits, and correlating the disappearance of radioactivity from the blood with the appearance of radioactivity in the bile.

Cæruloplasmin labelled *in vivo* was isolated from the serum of rabbits which had received copper-64 acetate intravenously on the preceding day. The copper-protein was freed of non-cæruloplasmin copper with sodium diethyldithiocarbamate[4] and purified by chromatography of DEAE cellulose[5]. For each experiment, 14-60 μg of cæruloplasmin–copper-64 was injected intravenously into an adult female rabbit. The biological half-life of cæruloplasmin was measured in 3 rabbits by periodically determining the radioactivity of serum. Six other rabbits received similar doses of labelled cæruloplasmin. The bile ducts of two of these (rabbits Nos. 1 and 2) were immediately cannulated with No. 90 polyethylene catheters, and complete collections of bile were obtained for 6 and 18 h, respectively, at which time the animals were killed and the radioactivity in the liver determined. The same procedure was followed in another rabbit (No. 4) except for delaying cannulation of the bile duct for 20 h following injection of labelled cæruloplasmin and collecting bile for a total of 3½ h. In a fourth rabbit radioactivity of the liver alone was determined 19 h after injection. Complete collections of urine and fæces were obtained in the remaining two intact rabbits for 67 h after injection of labelled cæruloplasmin, after which they were killed.

Half-life of cæruloplasmin in the rabbit. The half-life was found to be 44, 58 and 67 h in the 3 rabbits examined, for a mean value of 56 h. This last figure was used as the basis for calculating in subsequent experiments the amount of cæruloplasmin cleared from the circulation during any time.

Excretion of cæruloplasmin copper. Following intravenous administration of labelled cæruloplasmin, less than

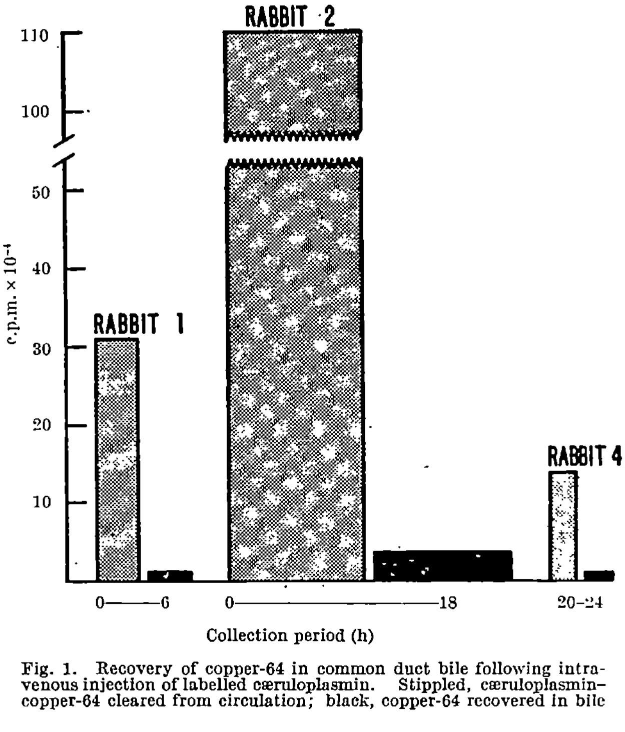

Fig. 1. Recovery of copper-64 in common duct bile following intravenous injection of labelled cæruloplasmin. Stippled, cæruloplasmin–copper-64 cleared from circulation; black, copper-64 recovered in bile

5 per cent of the fraction cleared from the circulation during the collection period was recovered in the bile whether cannulation was performed immediately following injection or delayed for 24 h (Fig. 1). When fæces and urine of 2 rabbits were collected for 67 h following administration of labelled cæruloplasmin less than 5 per cent of the radioactivity cleared from the circulation appeared in the combined collection from each animal.

Recovery of cæruloplasmin copper in liver. 17–70 per cent of the radioactivity cleared from the circulation during the interval between injection and killing was recovered in the liver (Fig. 2).

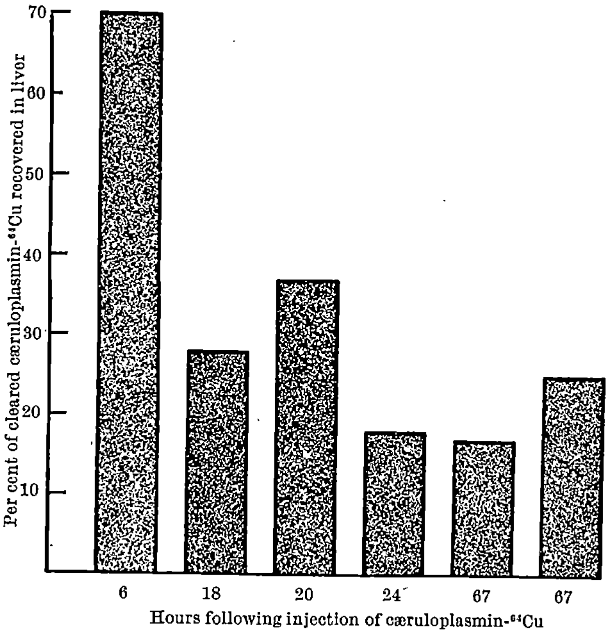

Fig. 2. Recovery of copper-64 in liver following intravenous injection of labelled cæruloplasmin

Because circulating cæruloplasmin does not renew or exchange its copper *in vivo*[4], the decline in radioactivity from the circulation following injection of copper-64-labelled cæruloplasmin is probably due to removal of molecules through metabolic degradation. Although a substantial fraction of the radioactivity cleared from the circulation was recovered in the livers of killed animals, only negligible activity was found in bile, fæces or urine. Thus, the copper of catabolized cæruloplasmin is not directly or preferentially excreted by hepatic, pancreatic, intestinal or renal routes in the rabbit.

Auditory Habituation in Cats as a Function of Stimulus Intensity

HABITUATION of the electrophysiological response in the cochlear nucleus (CN) to repetitive auditory stimuli has been reported by a number of workers[1–3]. Similar decrements were not obtained in a more recent study[4]. Marsh *et al.*[5], while reporting a decrement in the CN response, have shown increased responses to repetitive stimulation in the inferior colliculus (IC) and the medial geniculate (MG).

This investigation was designed to examine the effects of repetitive stimulation on the CN, IC and MG, and to determine whether any habituation obtained was a systematic function of stimulus intensity.

Using methods previously outlined[6], chronic implantations with stainless-steel bipolar electrodes were made in the CN, IC and MG of 25 cats. After allowing 3–4 weeks for recovery, the animals were stimulated in a sound-attenuated test box, which allowed behaviour to be monitored through one-way glass. The evoked auditory responses were recorded by an Offner EEG machine. Each trial consisted of presenting a 1,000 c/s tone of 20 msec duration every 2 sec for 95 min. Each animal was tested twice with four levels of intensity (55, 65, 75 and 85 decibels (db) as measured by a Dawe Sound Level Meter. Background sound pressure-level within the test box was approximately 45 db with respect to 0·0002 dynes/cm^2). To reduce any possible long-term effects, stimulus intensity was randomized over trials and the interval between consecutive trials was at least one week.

Recordings were taken every alternate 5 min and the overall amplitude of each evoked potential was measured and a mean score calculated for every 5-min period. These means were then expressed as a percentage decrement of a control value which was the mean of the initial four responses of a given trial.

Fig. 1 shows the mean plot for each placement as a function of intensity-level. Over all intensity-levels, it can be seen that the CN habituates less than the IC, which in turn habituates less than the MG. When the results for each centre are examined as a function of intensity-level, habituation in the CN and the IC is an inverse function of stimulus intensity. In the MG, the trend of the lower centres is reversed, and the greatest habituation occurs to the most intense stimulus.

Several conclusions can be drawn from these observations. (1) The nearer a placement is to the cortex, then the greater the degree of habituation. (2) Very little habituation occurs in the cochlear nucleus, and any marginal decrements obtained are restricted to tones of low intensity. (3) By using this method of repeated sampling over time, it can be seen that most of the habituation effect occurs in the first 40 min. In fact the reason for using a control period of the four initial responses was based on some preliminary experiments in which significant decrements were shown in the first minute of a trial.

It could be argued that our results are a function of the duration of our recording session. That is, the dramatic decrements obtained by other workers could be a function of longer periods of stimulation. However, experiments[7] in progress indicate that if the duration of a test session is extended to 8 h or 14,400 consecutive stimuli, then there is little increase in the level of habituation for a given stimulus intensity. Perhaps this apparent conflict with other results can be explained by observations made by Garcia-Austt *et al.*[8], who have pointed out that unless continuous averaging over time is used in the examination of habituation, then it is possible that "if . . . responses in the peak of a waning are compared with the superposed or averaged responses of the waxing peak of the subsequent cycle, the response amplitude may be the same or even higher". We have observed waxing and waning of response amplitude over time, and if only small

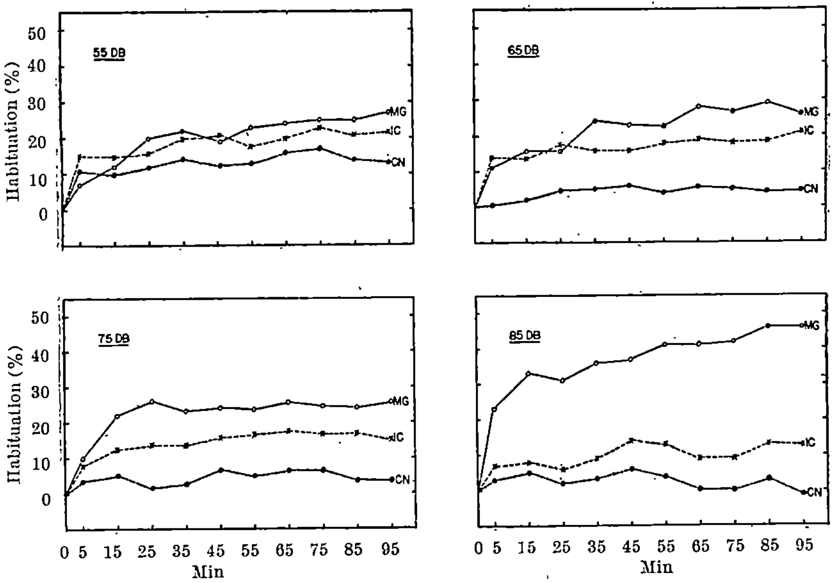

Fig. 1. Degree of auditory habituation, observed in the medial geniculate (MG), inferior colliculus (IC), and cochlear nucleus (CN) during 95 min of repetitive auditory stimulation at different sound intensity-levels

numbers of select responses are measured, then this could lead either to dramatic decrements or to significant increases over control-levels.

Synaptic Transmission at Taste Buds

Previous investigations have shown that a variety of sensory receptors can be stimulated by the application of acetylcholine[1], this sensitivity being enhanced in mechanoreceptors by the addition of 10^{-5} g/ml. physostigmine. Excitation by acetylcholine was blocked by tubocurarine or hexamethonium (10^{-7}–10^{-5} g/ml.)[2], but the response of the receptor to normal mechanical stimuli was unaffected by the presence of these blocking agents[1,2], and Gray and Diamond conclude, therefore, that acetylcholine has no physiological function as an intermediary in the initiation of nerve impulses at sensory receptors[1]. Landgren *et al.*[3], applying drugs to the surface of the frog's tongue, found, however, that high concentrations of anticholinesterases initially increased the spontaneous activity in the lingual nerve and afterwards blocked taste sensitivity. Tubocurarine also reduced the response of the taste buds to gustatory stimuli and these authors suggest that acetylcholine is concerned with the initiation of impulses at chemoreceptors.

Taste buds differ from mechanoreceptors in that a synaptic discontinuity exists between the chemoreceptor and its afferent neurone, the synapse having now been demonstrated by electron microscopy[4]. Davis[5] has presented a model for sense-organ excitation in which he suggests that, where such a synapse exists, stimulation produces a receptor potential which causes the liberation of a transmitter. On its arrival at the post-synaptic side, this transmitter produces a generator potential which initiates the action potential in the neurone. The differing results obtained with mechano-[2] and chemo-receptors[3] might, therefore, be explained by the action of acetylcholine as a transmitter in the latter, a hypothesis which is supported by recent histochemical localizations of cholinesterases in mammalian taste buds[6].

In the present experiments, recordings were made from the lingual branch of the glossopharyngeal nerve of frogs (*Rana temporaria*), as described by Landgren *et al.*[3], but the drugs were perfused through the lingual artery. Gustatory stimuli were applied to the surface of the tongue.

Perfusion of the tongue preparation with 10^{-4}–10^{-2} M 62*C*47 or with 10^{-5}–10^{-3} M iso-*OMPA* for 25 min did not reduce the sensitivity of the tongue to gustatory or tactile stimulation. Preparations perfused successively with 62*C*47 and iso-*OMPA* still responded normally. 62*C*47 and iso-*OMPA* are regarded as specific inhibitors for acetylcholinesterase and pseudocholinesterase respectively and the highest concentrations studied are 1,000 times those required for complete inhibition of these enzymes[7].

The general cholinesterase inhibitors physostigmine (10^{-7}–10^{-4} M) and neostigmine (10^{-6}–10^{-4} M) did not affect gustatory sensitivity when perfused for 15 min. However, the response to chemical stimulation was blocked by using either $1\cdot25 \times 10^{-3}$ M physostigmine (15 min) or the general esterase inhibitor, diethyl *p*-nitrophenyl phosphate (*E*600), at a concentration of 10^{-3} M (7 min). More dilute solutions of *E*600 did not have this effect. The blocking actions of both physostigmine and *E*600 were readily reversible.

d-Tubocurarine (10^{-3}–10^{-5} M), hexamethonium (2×10^{-2} M) and decamethonium (10^{-2} M), which are blocking agents for muscle endplates and autonomic ganglia, failed to reduce taste sensitivity on perfusion for 20 min.

It is impossible to determine the concentration of the drugs at the synapse under these conditions, but the taste buds respond readily to other substances injected in a similar fashion[8]. The concentrations of esterase inhibitors at which a block of taste sensitivity was obtained were very high indeed and probably reflect the block produced by high concentrations (2×10^{-3} M) of physostigmine in non-myelinated nerve fibres[9].

It is, therefore, unlikely that cholinergic transmission operates at the synaptic connexion between the taste bud and its afferent neurone. Possibly, some other form of specific chemical transmitter is liberated, or alternatively transmission may be electrical, as in the synaptic connexion in the abdominal ganglion of crayfish between the lateral giant axon and the segmental motor fibre[10].

PHARMACOLOGY

Effect of Excess of Antigen on the Active Anaphylactic Reaction *in vitro*

The similarities between the effects of the classic anaphylactic reactions and the reactions induced by antigen–antibody complexes suggest that there may be a similarity in the mechanisms responsible for these reactions. It is known that the ability of soluble complexes to produce anaphylactic reactions is governed by the quantitative relationship between antigen and antibody: the complexes prepared in slight-to-moderate excess antigen are most effective in producing anaphylactic reactions, whereas in greater than moderate antigen excess this effectiveness decreases with an increase in the amount of antigen added[1–3]. Recently, it has been shown that the passive anaphylactic reaction is inhibited by very large excesses of antigen[4,5]. In the present investigation on the release of histamine from actively sensitized peritoneal mast cells of the rat, it is shown that increasing excesses of antigen decrease the intensity of the anaphylactic reaction.

The rats were actively sensitized to ovalbumin using h. pertussis as an adjuvant. After 20 days at least of sensitization, heparinized saline or Tyrode's solution was injected intraperitoneally, the peritoneal fluid collected after gentle massage, and used after adequate dilution (about 20 mast cells per mm^3) in the experiments. In some cases, the peritoneal fluid was centrifugated and the sediment suspended again in Tyrode, or the mast cells were isolated from the other cells by differential centrifugation over a 30 per cent bovine serum albumin (BSA) solution. The antigen, 'Sigma' or laboratory ovalbumin crystallized three times, was added to the diluted mast cells suspensions after incubation for 15 min at 37° C. After a further 15-min incubation with the antigen, the cells were centrifuged, the supernatant completely drained and the sediment re-suspended and heated at 100° C for 3 min. The histamine released from the mast cells was biologically assayed both in the supernatant and in the sediment extract and expressed as a percentage of the total mast cell histamine content. The spontaneous histamine released was subtracted from the antigen one, each value being the mean of two tests.

The results of some typical experiments (Fig. 1) show that there is an optimum in the concentration of antigen, an excess of it inhibiting the histamine release. Controls involving the addition of a non-specific protein to the antigen solution (Fig. 1, III) showed that the inhibitory action was not caused by an excess of protein, but specifically by an excessive amount of the homologous antigen. Experiments showing that excess of ovalbumin had no effect on the release of histamine by various concentrations of 48/80 also confirmed the specificity of action of ovalbumin as an antigen. The inhibitory effect of excess of antigen was obtained in the same way with the isolated mast cells: in a typical experiment where concentration of the mast cells was 16 cells/mm^3 and purity in relation to other cells 90 per cent, 1 μg ovalbumin released 26 per cent histamine, 50 μg, 29 per cent and 2·5 mg, 4 per cent. It was verified that increasing the concentration of the mast cells removed the inhibition caused by the antigen excess (Fig. 2). Analysis of variance gave highly significant values of F for the effect of antigen, the effect of mast cells concentration, and the effect of interaction between them, suggesting that the effect of excess antigen depends on a quantitative relationship between the antigen added and the mast cells concentration.

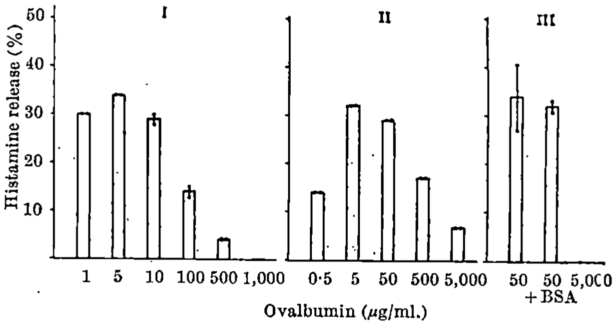

Fig. 1. Effect of antigen concentration on histamine release from actively sensitized rat peritoneal mast cells. Means with individual values are shown. Mast cells concentration = 19 cells/mm^3 in I, 33 cells/mm^3 in II, and 23 cells/mm^3 in III. BSA addition, 5 mg in III

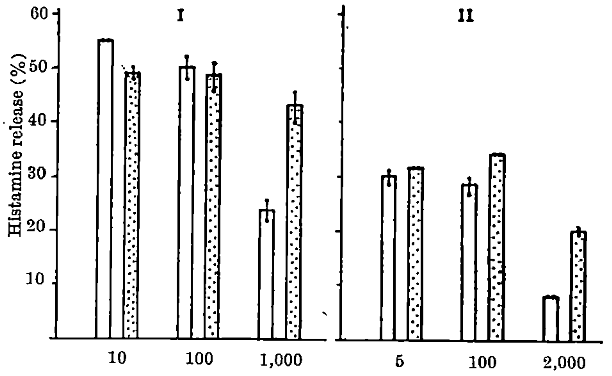

Fig. 2. Effect of antigen and mast cells concentration on histamine release from actively sensitized rat peritoneal mast cells. Means with individual values are shown. Mast cells concentration = 8·5 cells/mm^3 (white) and 85 cells/mm^3 (stippled) in I, and 7·7 cells/mm^3 (white) and 154 cells/mm^3 (stippled) in II

We did not succeed in obtaining an inhibition of the anaphylactic reaction in guinea pig or rat lung actively sensitized, nor the Schultz–Dale reaction, by addition of much larger excesses of antigen (25–100 mg/ml. for 100–200 mg tissue).

It has been demonstrated that antigen–antibody complexes formed with antigen concentrations more than 20–50 times that at equivalence are biologically inactive, while the most active ones are those formed in a zone where antigen is from 2 to 10 times in excess[1–3]. The ability of these complexes to release histamine from rat mast cells has been discussed by some authors[6,7]. In our experiments, it is not justifiable to compare the antigen/antibody ratios with those found in the soluble complexes, since the antibody was fixed to the tissue, and the antigen initially free in solution. Nevertheless, there is a strong suggestion that the anaphylactic reaction in the actively sensitized rat peritoneal mast cells would be initiated by a mechanism similar to that of the formation of a biologically active antigen–antibody complex.

Combination Chemotherapy with Actinomycin *D* and Ribonuclease : an Example of Complementary Inhibition

Two mechanisms have been suggested by which combinations of drugs may depress the intracellular availability of a given metabolite to a level that becomes limiting for cell survival. Potter[1] has applied the term sequential inhibition to the action of two or more inhibitors on different enzymes in a limited portion of a multi-enzyme sequence (equation 1), and Elion, Singer and Hitchings[2] have denoted as concurrent blockade

$$A \xrightarrow{\overset{I_1}{\downarrow}} B \xrightarrow{\overset{I_2}{\downarrow}} C \tag{1}$$

the simultaneous retardation, by two or more agents, of alternate biochemical routes to the same end-product (equation 2).

$$\begin{tikzcd} A \arrow[r, "\overset{I_1}{\downarrow}"] & B \arrow[dr] & \\ & & C \\ D \arrow[r, "\overset{I_2}{\downarrow}"] & E \arrow[ur] & \end{tikzcd} \tag{2}$$

An additional mechanism can be visualized whereby drugs capable of binding and inactivating macro-molecules (for example, nucleic acids and enzymes) within the cell are used in conjunction with other agents capable of altering biosynthetic pathways leading to the formation of an end-product that has been rendered partially or completely non-functional. This mechanism, termed complementary inhibition, will be illustrated in the present report by the action of combinations of actinomycin *D* and bovine pancreatic ribonuclease on sarcoma 180 ascites cells. The function of the ribonuclease is to hydrolyse enzymatically some of the existing ribonucleic acid (RNA) molecules within the cell, and that of the actinomycin *D* is to retard metabolic repair processes that involve the re-synthesis of the catabolized RNA. The relatively specific inhibition of deoxyribonucleic acid (DNA)-dependent RNA synthesis by actinomycin *D* has been reported by several investigators and the mechanism involved has been reviewed recently[3,4]. Such metabolic insult results in an inhibition of neoplastic cell growth[3,4]; however, survival of cells may ensue through conservation and utilization of pre-existing RNA molecules for metabolic function. The addition of ribonuclease, an enzyme reported to arrest temporarily the growth of several transplanted or spontaneous rodent neoplasms[5], to the actinomycin *D* therapy depletes cellular RNA content further by depolymerizing some of the RNA formed prior to the actinomycin *D* blockade.

* Administered intraperitoneally once daily for 6 consecutive days, beginning 24 h after implantation of tumour cells, with combined treatments given simultaneously. Mice were maintained throughout the experiments on drinking water containing 40 μg streptomycin/ml.

† Average weight change from onset to termination of drug treatment.

‡ Mice surviving over 50 days were calculated as 50-day survivors in determination of the average survival time.

The effects of such combinations on neoplastic growth were measured in adult *C3H* mice that had received approximately 4 × 10^6 sarcoma-180 ascites tumour cells by intraperitoneal injection as previously described[6]. Therapy was initiated 24 h after implantation of the neoplastic cells and was continued for six consecutive days. Therapeutic efficacy was determined by the prolongation of survival time afforded by drug treatments and by the number of mice surviving for at least 50 days. The percentage weight change from onset to termination of therapy was used as an indication of drug toxicity. The results in Table 1 indicate that commercial 3-times recrystallized bovine pancreatic ribonuclease, given intraperitoneally, did not prolong the survival time of sarcoma-180 tumour-bearing mice in daily doses up to 200 mg/kg of body-weight. Actinomycin *D* prolonged life over a range of doses; however, only a few mice survived for 50 days. Several combinations of the two agents resulted in pronounced synergistic inhibition of this neoplasm; toxicity as manifest by weight loss was comparable with that caused by actinomycin *D* alone. Combinations of actinomycin *D* with up to 200 mg of bovine serum albumin per kg, included as a control, yielded results comparable with those achieved with actinomycin *D*.

The results of experiments measuring the effects of drug therapy on the RNA content of sarcoma-180 cells are shown in Table 2. Since cells exposed to ribonuclease had a tendency to agglutinate, the average content of

Table 2. EFFECT OF ACTINOMYCIN D AND RIBONUCLEASE ON THE NUCLEIC ACID CONTENT OF SARCOMA-180 ASCITES CELLS

Treatment	Relative content, RNA/DNA Exp. 1	Exp. 2	Exp. 3	Exp. 4	Exp. 5
None	100	100	100	100	100
Ribonuclease	89	76	88	86	80
Actinomycin D	45	51	47	54	45
Actinomycin D + ribonuclease	38	39	40	44	39

Drugs were administered intraperitoneally to tumour-bearing mice beginning 4 days after implantation of ascites cells; three doses were given 48, 24 and 12 h, respectively, before analyses of nucleic acid content. Actinomycin *D* was used at 0·06 mg/kg/dose in all experiments, while ribonuclease was used at 240 mg/kg/dose in experiments 1, 2 and 3 and at 320 mg/kg/dose in experiments 4 and 5. Concentrations of DNA and RNA were determined by pentose analyses (ref. 10), using deoxyadenosine and adenosine as the standards, respectively. Untreated sarcoma-180 ascites cells contained 31·2 mμmoles of DNA deoxyribose/10^6 cells and 213·8 mμmoles of RNA ribose/10^6 cells.

Each value represents the average of results obtained from the separate analyses of ascites cells from 3–4 mice.

RNA per cell could not be calculated for every sample; the results, therefore, are expressed as the relative concentration of RNA/DNA. In samples in which accurate cell counts could be achieved, the DNA content of cells exposed to the various treatments were comparable with the control levels. In all the experiments, ribonuclease produced a slight depression of the RNA content, while actinomycin *D* caused a pronounced decrease in RNA. The combined treatment of ascites cells resulted in a depletion of the cellular RNA content that was greater than that caused by either drug alone. Although the decrease in RNA content induced by the drug combination was sub-additive, it is evident that such a level of depletion may well be critical for cellular survival and that synergistic growth inhibition may be the result. In contrast, bovine serum albumin (320 mg/kg/dose) did not augment the decrease in RNA content produced by the actinomycin *D*.

Other examples of the complementary inhibition, involving DNA, appear to be provided by the finding that combinations of uracil mustard (5-*bis*[2-chloroethyl]amino-uracil) with certain antimetabolites yield enhanced inhibition of the growth of several murine neoplastic cell lines[7,8] and by the report that synergistic inhibition of the growth of sarcoma-180 was achieved by combinations of mitomycin *C* with either 5-fluorouracil or 6-thioguanine[9]. Thus, theoretically, the use of complementary inhibition in the rational selection of combinations of drugs as potential synergistic inhibitors of neoplastic growth would appear to warrant further investigation.

This work was supported by a grant (*CA*–02817) from the National Cancer Institute, U.S. Public Health Service. Actinomycin *D* was kindly supplied by Dr. C. A. Stone, Merck Sharp and Dohme, West Point, Penn.

Interrelationships between Amphetamine and *Harmala* Alkaloids

It has been shown[1] that iproniazid increased the hypertensive effects of indirect sympathomimetic amines, without altering significantly those of the directly acting catecholamines. We suggested later[2] that monoaminoxidase inhibitors could facilitate the release of catecholamines induced by indirectly acting sympathomimetic amines. In this communication it is reported that two *Harmala* alkaloids, harmaline and harmine, which are both monoaminoxidase inhibitors with a rapid and brief action, can release catecholamines under certain conditions.

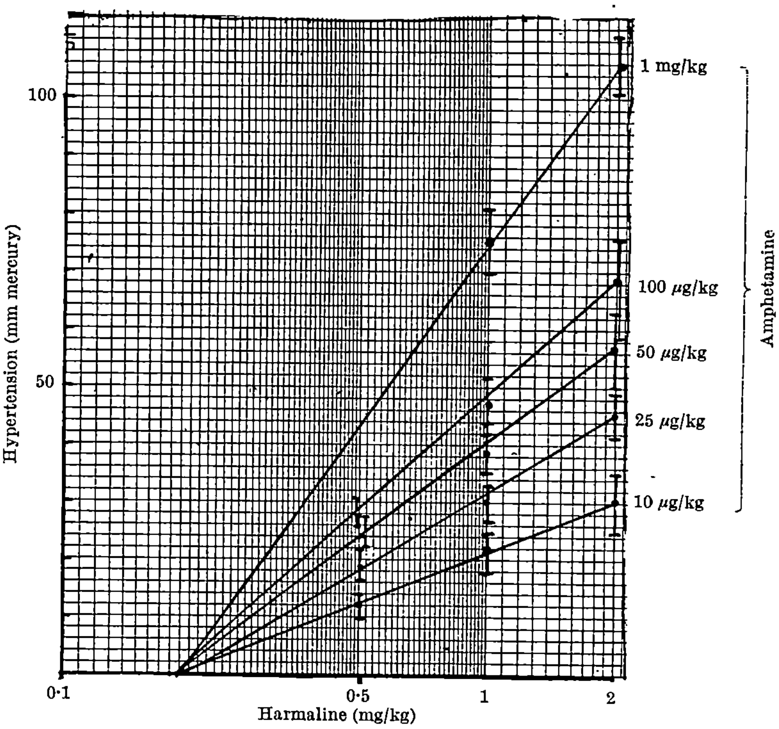

Fig. 1. Hypertensive effect of harmaline after various doses of amphetamine

Our experiments were performed on pithed rats prepared according to the method of Shipley and Tilden[3]. The blood pressure was recorded from a carotid artery using Condon's mercury manometer.

Injections of 0·5–2 mg/kg of harmine or harmaline potentiated very strongly the pressor responses to small doses of amphetamine but decreased the responses to large doses. A similar potentiation by harmaline was observed on pressor responses to phenylethylamine, tyramine, ephedrine, bretylium and guanethidine.

When harmaline and harmine were injected after the rats had been given a very small dose of amphetamine, they produced a marked increase in blood pressure, instead of the usual small one (8–10 mm mercury). Fig. 1 shows the relationships between the hypertensive effect of harmaline and the dose of amphetamine previously injected. The duration of this hypertensive effect of harmine and harmaline increased with the doses of amphetamine given. After producing a response by injection of a *Harmala* alkaloid, a second response could be produced by another injection of the alkaloid, but the second hypertensive response was smaller when higher doses of harmine or harmaline were used.

The increased hypertensive response to *Harmala* alkaloids could also be elicited by previous injections of bretylium (5 mg/kg), or guanethidine (5 mg/kg), or pheniprazine (2 mg/kg), but tyramine and phenylethylamine had no action.

The rise in blood pressure induced by either *Harmala* alkaloid after amphetamine was not changed by bilateral adrenalectomy; but it was abolished by treatment with phenoxybenzamine, and it could not be elicited in the rat pretreated 24 h previously with reserpine (10 mg/kg) in order to deplete the noradrenaline stores. From these observations it could be concluded that *Harmala* alkaloids release noradrenaline from peripheral stores after previous injection of amphetamine.

This noradrenaline-releasing effect of *Harmala* alkaloids does not seem to be related to their property of inhibiting monoaminoxidase for the following reasons: (*a*) Previous injections of harmaline and harmine (2 mg/kg) increased the pressor responses to amphetamine, but did not change the hypertension induced by *Harmala* alkaloids after amphetamine. Similar observations were made on the rat in which monoaminoxidase had been inhibited by previous administration of pheniprazine (5 mg/kg) or iproniazid (50 mg/kg, given 24 h previously). (*b*) Amphetamine did not increase but decreased the hypertensive effect of another monoaminoxidase inhibitor, pheniprazine.

In summary, harmine and harmaline can produce a release of catecholamines in rats previously given amphetamine; but this property seems to be unrelated to their action in inhibiting monoaminoxidase. We suggest that amphetamine not only induces release of catecholamines but also, even at very small doses, it changes the form of storage of catecholamines, making them available for release by *Harmala* alkaloids. We have previously shown that amphetamine has a similar action in making catecholamines more readily releasable by reserpine[2].

HISTOCHEMISTRY

Localization of Invertase Activity in Small Intestinal Cells

As has been shown, the hydrolysis of disaccharides is accomplished by enzymes associated with certain structures of the intestinal epithelium cells. A more exact localization of the action of disaccharidases in the intestinal epithelium cells leads to some controversy between different authors.

Based on the investigation of hydrolysis of disaccharides it was suggested that the hydrolysis occurs inside the cells or in defined cytoplasmatic structures, which sediment together with the microsome fraction[1,2] or are located on "the inner aspect of the inner limiting membrane of microvilli"[3,4].

According to another point of view, the final stages of hydrolysis develop on the external surface of the cell membrane by means of membrane or contact digestion[5,6].

The concentration criterion which was successfully used by Rothstein[7] for the determination of invertase localization in yeast cells is a reliable argument for deciding which hypothesis is correct.

Indeed, if the hydrolysis occurs inside the cells, the accumulation of monosaccharides in tissue should be independent of its concentration in the medium during the course of incubation. If, on the other hand, the comparative examination of reaction products in tissue and in the solution reveals a higher concentration in the extracellular fluid, one would expect that the hydrolysis occurs extracellularly or at least on the surface of the mucosa. If we consider that the hydrolysis of disaccharides occurs on the mucosal surface, the uptake of monosaccharides should depend on the medium concentration.

The complete reliability of this criterion is only possible in cases of a smooth surface. In the case of the intestine, one has to keep in mind that the architecture of villi and microvilli hinders the diffusion of reaction products into the main volume of the incubation solution and contributes mainly to the passage of the substances into the cells.

A second restriction should be made: If the volume of the extracellular fluid largely exceeds the tissue volume the final concentration of hydrolysis products in the extracellular solution will depend not only on the localization of the hydrolytic enzymes but also on the dilution as well.

In the present investigation we repeated the data obtained by Miller and Crane. The extracellular and intracellular concentrations of hexoses after incubation in sucrose were compared. We developed a technique which enabled us to determine the concentration of hexoses in the immediate neighbourhood of the membrane.

Weighed pieces of everted intestine of white rats (Wistar strain), previously poisoned with sodium fluoride (0·02 per cent) to prevent active transport, were incubated in 2 per cent sucrose–Ringer's solution (*p*H 7). In order to increase the hydrolysis, the incubation solution was shaken. The concentration of reducing sugars both in tissue homogenates and in the extracellular solution was determined by the method of Nelson.

As we were technically unable to examine by this method reaction-rates for rather small extracellular fluid volumes (0·2–0·5 times the tissue volume), we changed this method as follows. An everted piece of intestine was dipped during 30 sec in a sucrose–Ringer solution (2 per cent) and the excess of fluid was discarded. The wet piece of intestine was laid on a plastic square with its wet mucosa uppermost, and covered with another plastic sheet to prevent evaporation. After a known incubation time (2–20 min) the cover was taken off and the mucosa was gently dabbed with a weighed piece of filter paper or lens-paper. (The histological preparation shows that the villi structure was not injured in these experiments.) The tissue was immediately homogenized and the wet paper was reweighed. In both tissue and paper the reducing activity was determined by Nelson's method.

By this method we were able to examine the incubation of small volumes of solution (up to 10 µl.) on 100–200 mg pieces of intestine and to compare the hexose concentration near the surface of the villi (mainly apical fluid) and in the upper part of the intervilli cavity with the hexose concentration in the tissue.

In the first part of this work, the experimental conditions used by Miller and Crane[3,4] were reproduced. Pieces of intestine were incubated in a sucrose solution which exceeds several times its own volume. In this case the observations of Miller and Crane were confirmed. We observed that the concentration of the hexoses formed in the tissue does not depend on the volume of the incubation medium. The concentration of hexoses in the surrounding medium is inversely proportional to its volume.

In the second part of this work we tried to determine the monosaccharide concentration in the immediate proximity of the external side of the membrane. In the case of the intracellular hydrolysis the concentration of hexoses in the external solution ought to be lower than the intracellular one (shaded area, Fig. 1). During a prolonged incubation time a relative increase in the hexose concentration in the surrounding medium was expected. This was shown by Miller and Crane[3,4]. However, as can be seen from Fig. 1, the concentration of monosaccharides in the extracellular fluid near the surface of the villi is higher than in the intracellular water. This fact can scarcely confirm the concept of intracellular hydrolysis of sucrose.

The dynamics of concentration ratio, at various incubation periods, showing a gradient reverse from that described by Miller and Crane, strongly supports the extracellular membrane digestion of sucrose. Indeed, in the first incubation minutes, the extracellular hexose concentration exceeds four times the tissue concentration. This fact can scarcely be explained as a consequence of diffusion of hexoses from the cell to the extracellular fluid against a concentration gradient of this strength.

The ratio decreases to a steady state of 2–2·5 for 20 min and remains constant due to the enzymatic activity.

We readily accept that this method cannot give a true image of the hexose content in the liquid which is present in the brush border pores. Our results are only an approx-

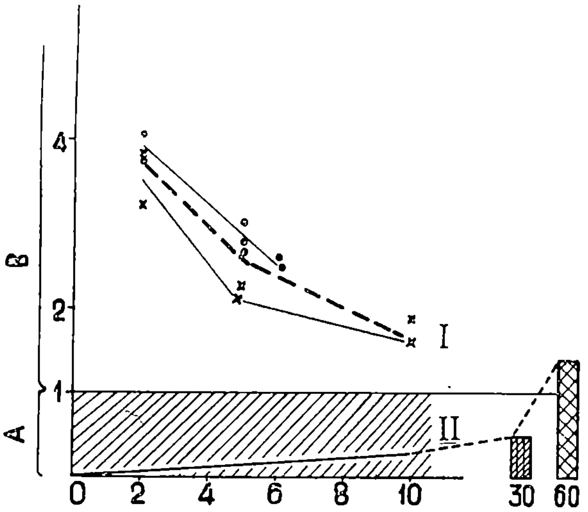

Fig. 1. Concentration ratio of hexoses liberated during sucrose hydrolysis in the incubation solution and in the intracellular fluid. imation to the characteristics of the true concentration gradient. It is logical to assume that the hexose concentration on the external surface of the cell membranes should be higher than that we have observed in our experiments.

The results obtained by Miller and Crane rather reflect the dilution than the true distribution of substances on both sides of the cell membrane.

This concentration difference (solution/tissue) is independent of the length of the used intestine piece as we observed the same ratio for pieces of 1 cm as for pieces of 8 cm length (Fig. 2).

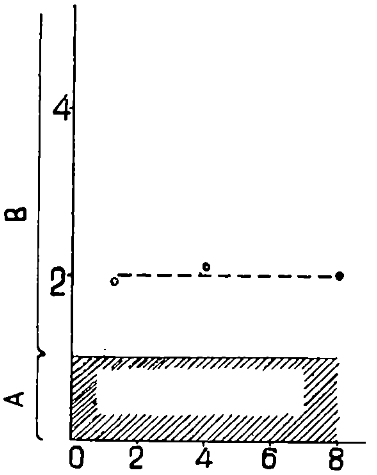

Fig. 2. Relationship between the concentration ratio of hexoses liberated during sucrose hydrolysis and the length of the everted pieces of intestine. Abscissa: length of intestinal pieces (cm); ordinate: concentration ratio of hexoses in incubation solution versus intracellular liquid

If one considers the disaccharides absorption mechanism to consist of at least three steps—the passive transport of disaccharides into the mucosal cells, its hydrolysis inside the cell and the active transport of monosaccharides through the cell into the portal blood—it can be postulated that, after inhibition of the active transport and preventing the destruction of reaction compounds *in situ*: (1) the accumulation of monosaccharides in the tissue is independent of the concentration in the medium; (2) the monosaccharides ought to appear first inside the cell and after a while, by diffusion, an equilibrium must be reached between hexose concentration on both sides of the membrane; (3) the accumulation of monosaccharides in the tissue depends on the amount of tissue used.

If one considers, on the other hand, the disaccharides absorption mechanism to consist of at least two steps—the membrane-bound surface hydrolysis followed by an active transport of monosaccharides—facts contrary to the first postulation ought to be expected.

In this series of experiments it can be observed that: (1) The hexoses appear first in the surrounding medium before they enter by diffusion in the tissue (Fig. 1). (2) A concentration gradient in hexose concentration between the bulk of the phase and the apical part of the mucosa was observed in the solution. (3) The accumulation of monosaccharides is independent of the length of the piece of intestine used (Fig. 2).

Using the reliable concentration criterion, we may assume that the true locus of sucrose digestion is on the external part of the limiting membrane of the intestinal epithelium, as has been shown by Ugolev *et al.*[8].

HÆMATOLOGY

Interaction of Mercuric Ion with Hæmoglobin

The reactivity of the sulphydryl groups of human hæmoglobin has been examined in many laboratories. Recently, Cecil and Snow[1] have reported spectral changes in 6 M urea at *p*H 9 when 8 equivalents of $HgCl_2$ are added to oxyhæmoglobin (HbO_2) and metHb at 37° C. In the course of investigations in this Laboratory on the effect of $HgCl_2$, it was observed that the addition of more than 10 equivalents of mercury per hæmoglobin produces marked changes in the absorption spectra and the rotatory dispersion curves of both HbO_2 and metHb. The final product, in both instances, is similar to acid-denatured protein. Hardman and Gurd[2] have made essentially the same observations when copper or zinc reacts with metmyoglobin.

Hb*A* was prepared from cells washed with 0·9 per cent sodium chloride and lysed in water. The solution was deionized by dialysis and electrodialysis. Methæmoglobin was prepared by the method of Mirsky and Anson[3] with some modifications. Only 1·5 equivalents of $K_3Fe(CN)_6$ were used; the solution of metHb was deionized by dialysis against 0·05 M phosphate buffer *p*H 6·8 until the yellow colour was no longer visible, then dialysed against water, and finally electrodialysed. Absorption spectra were obtained at room temperature in a Cary, model 14, spectrophotometer. Rotatory dispersion curves were obtained using Bendix–Ericsson and Rudolph recording spectropolarimeters at room temperature (24°–25° C).

The absorption spectra obtained when HbO_2 was the starting material are given in Figs. 1 and 2. The addition of dilute acid to adjust the *p*H to 3 produced a marked decrease in intensity in the Soret region coupled with a shift to shorter wave-lengths (Fig. 1). The final absorption spectrum, obtained in about 2 h, had a single broad maximum between 370 and 390 mμ. This curve is virtually indistinguishable from that of hæmin (Fig. 2). When $HgCl_2$ was added to a solution of HbO_2 and the *p*H maintained between 5·5 and 5·8 during the addition of the mercury solution, the absorption spectra were similar to those seen in the early stages of acid denaturation. By maintaining the *p*H in a range where *p*H alone did not affect the absorption spectra it was therefore possible to separate the effects due to Hg (II) from those due to *p*H. The addition of $HgCl_3$ in ratios of 10–100/1 ($HgCl_2$/protein) gave similar results. With some variations, such as the degree of change observed at comparable ratios of Hg/protein, metHb gave the same general results. Sperm whale myoglobin gave the same spectral changes when $HgCl_2$ was added.

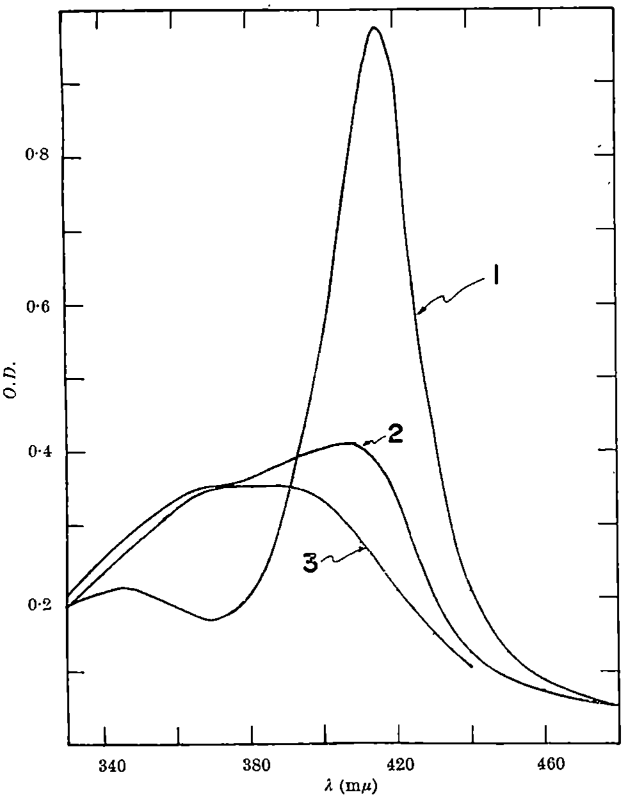

Fig. 1. Absorption spectra of HbO_2. Curve 1, *p*H 6·8; Curve 2, *p*H 3 after 30 min; curve 3, *p*H 3 after 1 h

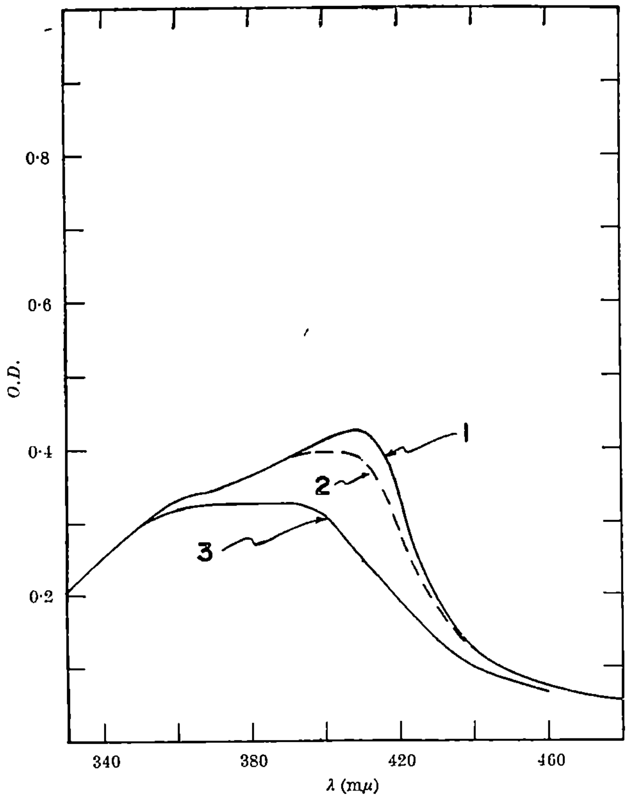

Fig. 2. Absorption spectra of HbO_2 plus $HgCl_2$ and hæmin. Curve 1, HbO_2 + $HgCl_2$ 40/1 after 30 min; curve 2, after 1 h, 3 h, and 9 h; curve 3, hæmin *p*H 5·8

The rotatory dispersion data indicated that the specific rotations of acid-denatured HbO_2, acid-denatured metHb, HbO_2 plus 50 equivalents of $HgCl_2$, and metHb plus 50 equivalents of $HgCl_2$ were all more negative than HbO_2 and metHb above 270 mμ and less negative below this wave-length. The values of the specific rotation at 233 mμ, which were obtained using the Bendix–Ericsson, are listed in Table 1. It can be seen that the addition of $HgCl_2$ as well as acid denaturation result in less negative values for the calculated parameter. In addition to these characteristics in the ultra-violet region, the Cotton effect in the Soret region is absent in acid-denatured protein and in protein plus $HgCl_2$.

Table 1

Protein	*p*H	Ionic strength	Hg/ protein	b_0*	$(\alpha)_{233m\mu}$
HbO_2	5·8	10^{-4}	—	−550	−9,200
	3	0·002	—	−75	−3,740
	3	0·002	—	−125	
	3→6	0·004	—	−550	−7,020
	5·8	10^{-4}	40/1	−417	−4,700
			90/1	−210	
MetHb	5·9		—	−517	
	5·9		—	−470	
	3	0·002	—	−25	
	3	0·2	—	−156	
	5·9	2×10^{-4}	50/1	−127	
MetMb	5·6	0·002	—	−550	
	5·6	0·002	20/1	−350	

* Calculated using $\lambda_0 = 212$ mμ.

From the data between 240 and 300 mμ Moffitt–Yang plots were drawn. The values of b_0 calculated from the slopes of these curves are listed in Table 1. It can be seen that both acid denaturation and the addition of $HgCl_2$ result in less negative values of b_0. Values calculated for human ferrihæmoglobin are similar to those reported by Beychok *et al.*[4] for horse ferrihæmoglobin. In addition, the effect of ionic strength is similar to that found by them. However, the ionic strength effect is not of sufficient magnitude to make any significant contribution to the changes seen in the presence of $HgCl_2$ under the conditions of these experiments and at the concentrations used (10^{-4} M). Similar observations have been made with sperm whale myoglobin (Table 1).

As evidenced from the absorption spectra both in the Soret region and at 630 mμ, metHb formed on the addition of $HgCl_2$. If the *p*H of acid-denatured hæmoglobin was raised from 3 to 5·8, both the absorption spectra as well as the rotatory dispersion indicated that there had been a 'renaturation'[5] of the protein.

From the changes in the absorption spectra, as well as the optical rotatory properties, it appears that Hg (II) produces effects that are qualitatively similar to those due to acid denaturation. This, coupled with the fact that the environment of the hæm group has been affected, suggests that histidine residues are involved[6,7]. Experiments in progress using nitrophenylacetate, the hydrolysis of which is catalysed by imidazole[8,9], indicate that imidazole residues are made unavailable when $HgCl_2$ is added to metHb. The rate of hydrolysis of the ester by metHb is 1·5–2 times more rapid in the absence of $HgCl_2$ than in the presence of it ($HgCl_2$/protein = 6/1). As a result, at the present time, it seems that $HgCl_2$ is capable of reacting not only with the sulphydryl groups but also the imidazole residues of hæmoglobin.

PATHOLOGY

Effect of RNA on Vascular Permeability in the Rat

Previous workers have shown that certain nucleosides and nucleotides can increase vascular permeability and cause leucocyte emigration[1–4] and thereby directed attention to their potential role as mediators of inflammation.

An extract has recently been prepared from lymph node cells (LNPF) which causes an intense increase in vascular permeability and immediate and prolonged emigration of leucocytes and the deposition of a material resembling connective tissue fibrinoid[5]. Immediately following the injection of LNPF the inoculum reacts positively for RNA with the Unna–Pappenheim stain. After 20 min, however, the positive RNA reaction can no longer be obtained.

Because of these findings it was decided to investigate the ability of RNA and also DNA to reproduce the effects of lymph node extracts. Highly polymerized DNA from calf thymus (B.D.H.) failed to increase vascular permeability in the rat in doses of 15 µg to 5 mg/ml. On the other hand, a purified preparation of highly polymerized yeast RNA (B.D.H.)[6] was active in increasing vascular permeability over the range of 15 µg–1 mg/ml. This preparation of RNA also induced extensive emigration of leucocytes within 15 min of injection, 100 µg leading to the accumulation of about 50 leucocytes per high power field. By 24 h after an injection of 100 µg of RNA, large numbers of mononuclear leucocytes were infiltrating the inoculation site. Unlike LNPF, however, injections of RNA did not lead to the accumulation of an eosinophilic coagulum at the site of injection. The effect of RNA on vascular permeability could not be destroyed by prior incubation with 1·5 mg/ml. ribonuclease (Sigma 50 units/mg) at 37° C for 1 h.

Unlike nucleosides, the effects of which appear to be due to release of histamine[3,4], the increase in vascular permeability induced by RNA could not be abolished by systemic dosage with the antihistamine drug mepyramine maleate ('Anthisan' 1–2·5 mg/kg) or the 5-hydroxytryptamine antagonist '*BOL* 148'. However, incubation of RNA with guinea pig plasma led to a striking suppression of its effect on vascular permeability as did local administration of sodium salicylate 2·5 mg/ml.[7]. In its response to these antagonists RNA bore a close resemblance to LNPF[8].

Other forms of RNA were found at first not to share the activity of the highly polymerized preparation, thus freshly made solutions of soluble yeast RNA sodium salt (B.D.H.) and soluble yeast RNA Type III (Sigma Co.) both failed to increase vascular permeability significantly when tested in rats' skin. On the other hand, when these same solutions were allowed to stand at room temperature, Seitz filtered and tested in rat skin, there was a progressive increase in activity, until after 24 h their effects were as great as that of the highly polymerized preparation. The effect of the aged solutions could not be attributed to the appearance of histamine-releasing nucleosides[4] since dye leakage was not diminished by administration of mepyramine maleate (2·5 mg/kg). The true explanation of this phenomenon is not yet apparent.

Nevertheless the results so far are consistent with the view that RNA or a derivative, for example, an oligonucleoside, might be responsible for some of the phlogistic effects of extracts of lymph nodes and perhaps other tissues.

We thank Prof. H. O. Schild and Dr. R. Mathias for their advice. This work was supported by grants from the Nuffield Foundation and the Medical Research Council.

Early Regressive Changes during the Tuberculin Skin Reaction

For an understanding of the pathogenesis of pathological processes, the initial stages of their development are usually most important. At first only the direct sequelæ of the causal agent play a part, and the position is not very complicated by regulatory and reparative processes aiming at the renewal of the normal state. The morphology of early stages of the hypersensitivity reaction of the delayed type has been examined by several authors[1–4], who directed attention mainly to the composition of the cell infiltrate. Because inflammatory infiltration is a result of tissue damage, I was interested rather in changes in tissues where the immunological reaction takes place.

I used white guinea pigs weighing 250–350 g, sensitized by injection of 0·1 ml. emulsion into both hind limbs of the following composition: 6 ml. paraffin oil, 2 ml. lanolin, 3 ml. physiological saline containing per 1 ml. 3 mg BCG vaccine killed by heat (1 h at 70° C). The skin tests were carried out 21–28 days after sensitization with 10, 1 and 0·1 µg PPD (Statens Seruminstitut, Copenhagen, Denmark) in 0·1 ml. physiological saline into the skin of the hip. The groups formed by five sensitized and one control guinea pig were killed 1/2, 1, 2, 3, 6, 12 and 24 h following the skin test. The sites of the skin test were examined in histological preparations stained with hæmatoxylin-erythrosin.

The inflammatory infiltrate was practically of equal composition to that described by Gell and Waksman[1,2]. The first changes, that is, leukostasis and leukodiapedesis, were found after 1 h around the subcutaneous venules. Gradually the infiltration of the subcutaneous tissue became diffuse and spread through the dermis underneath the epidermis. The composition of the infiltrate changed, depending on the dosage. When large doses were used neutrophils predominated; when small doses were applied an almost pure mononuclear infiltrate was formed around the subcutaneous venules. The changes in the subcutaneous fat were striking. Already after 2 h and sporadically even after 1 h I found lipophagic foci made up of macrophages surrounding, in a wreath-like fashion, the fat vacuole of the dead cell—partly of foreign body giant-cells, containing sometimes in their plasma optically vacant spaces after extraction of fat. In some larger lipophagic foci microabscesses were found, that is, an accumulation of neutrophils in a space corresponding to the size of the fat cell. The lipophagic foci appeared most frequently after medium or low doses of PPD or at the margin of the reaction to a larger dose. In the reaction with 10 μg PPD I found, after 2 h, several small foci of necrotic subcutaneous adipose tissue—an anuclear mass staining pale pink with erythrosin, with a sharp borderline at the adipose tissue which was only slightly infiltrated with polymorphs. Mononuclears were not represented. In subsequent specimens I did not find any necrosis foci; they were probably covered with a dense inflammatory cellulization. In non-sensitized controls there were neither necroses nor lipophagia.

The immunological reaction between sensitized cells and antigen takes place at the site where they meet. In the skin test these cells meet the antigen in the immediate vicinity of fine subcutaneous venules[5], which usually are next to the layer of subcutaneous adipose tissue. One of the consequences is damage of subcutaneous tissues which may manifest itself after larger doses of antigen by necrosis and after lower doses by a lipophagic reaction around individual dead or damaged cells. The observed regressive changes can be interpreted in two ways: (1) adipose tissue binds the antigen and the sensitized cells therefore attack it and break it down; (2) the subcutaneous adipose tissue is the only medium where the reaction takes place and it is damaged by the reaction products.

A hypothesis similar to the foregoing interpretation was elaborated by Waksman for the pathogenesis of experimental allergic encephalomyelitis. He assumes that sensitized monocytes (and histiocytes) attack and finally break down structures containing antigen[6]. It can be assumed that fat cells bind antigen; it cannot be concluded, however, from the fact that macrophages remove adipose tissue that they also attack and damage fat cells. The first hypothesis does not explain the observed early necroses, in the vicinity of which I did not find a striking accumulation of mono- or histio-cytes, but only a few polymorphs.

The second hypothesis has some points in common with the explanation of Goldberg *et al.*[7]. We assume that immunologically competent cells, after leaving the blood vessel, meet the antigen and liberate some biologically active substances which act as a mediator of the delayed hypersensitivity reaction. The mediator acts on the cells of the surrounding tissue and at higher concentrations it damages and kills them. The dead cells liberate further active principles, causing a reactive inflammation. In my own opinion, its character will not depend any more on the type of reaction which produced it but rather on its intensity rate, course and duration. Changes in adipose tissue are most striking because the reaction takes place in the immediate vicinity of fat cells and because adipose tissue is metabolically more active than fibrous tissue of the dermis. I believe that this hypothesis, though not yet confirmed, so far best agrees with the observed facts.

Nucleolus-like Inclusions in the Cytoplasm of HeLa Cells treated with Puromycin

Cytoplasmic inclusions containing RNA have been noted in HeLa cells treated with puromycin[1], an antimetabolite which is a selective inhibitor of protein synthesis[2,3]. It is now clear that these inclusions appear in a large proportion of treated cells when high concentrations of puromycin are used, and that these structures bear a resemblance to nucleoli as regards morphological appearances and their dependence on continued synthesis of cellular RNA.

Inclusions were produced in HeLa cells grown in monolayer culture under conditions described by Wildy *et al.*[4]. Unless otherwise stated in the protocol, 100 μg of puromycin dihydrochloride (Nutritional Biochemical Corp., Cleveland, Ohio) was present in each 1 ml. of the culture medium and the duration of action was 24 h. The inclusions were observed under phase contrast optics in unfixed cells, but were best visualized by any standard staining procedure for RNA. In the experiments described here the coverslips were fixed in 5 per cent trichloroacetic acid for 10 min, and stained for 15 min in 0·1 per cent aqueous toluidine blue at *p*H 5·5. The cells did not stain by this method after pretreatment with ribonuclease.

The production of inclusions by puromycin was concentration dependent (Fig. 1). Prolonged treatment with puromycin at concentrations lower than 5 μg/ml. did not result in the appearance of inclusions, although protein synthesis is known to be approximately 80 per cent inhibited within 45 min of the addition of puromycin[5,6]. The inclusions were formed at concentrations of puromycin higher than 5 μg/ml., and their numbers increased with concentration of puromycin until a maximal effect was reached at 50 μg/ml. of puromycin. This concentration has been shown to produce maximal inhibition of protein synthesis in HeLa cells[5,6]. This suggests that the

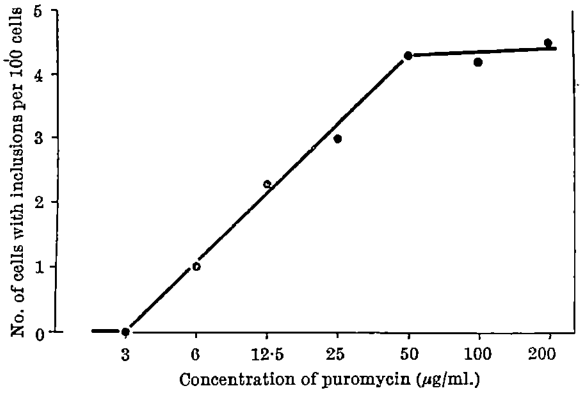

Fig. 1. Effect of concentration of puromycin on the frequency of cells with cytoplasmic inclusions. Duration of treatment was 4 h. The points shown are arithmetical means of values obtained in four separate experiments

appearance of cytoplasmic inclusions resulted from the interruption of protein synthesis.

The inclusions were first detected after treatment for 2 h with puromycin (Fig. 2). Their numbers increased gradually for 10 h, and at that time more than 30 per cent of the cells contained at least one inclusion. Thereafter, the proportion of cells with inclusions decreased slightly, and cells were being lost from the culture monolayer. Virtually all cells detached from glass after 48 h of treatment with puromycin.

The inclusions produced by puromycin are shown in Fig. 3. There was some variation in the appearance of cytoplasmic bodies produced by puromycin but a number of them were similar to the nucleoli in their size, in their ovoid or irregular shape, and in the intensity of staining with basophilic dyes. The inclusions were surrounded by an unstained area. In these respects they resembled cytoplasmic structures described by other workers as nucleoli extruded from the nucleus[7-10].

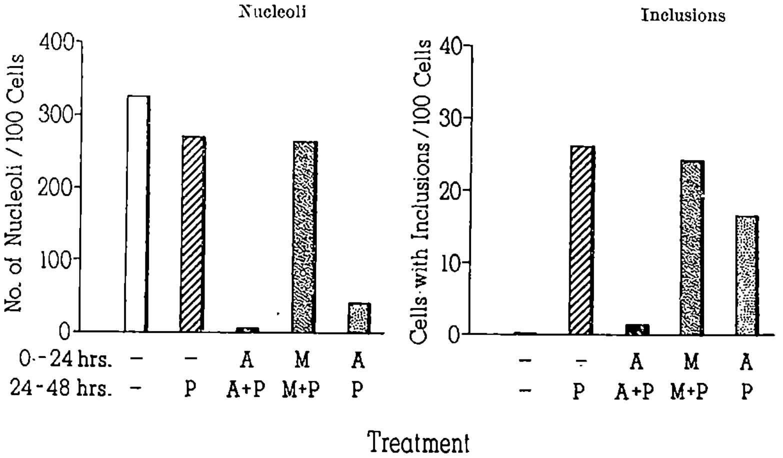

Fig. 4. Effect of pretreatment with actinomycin *D* (*A*) and mitomycin *C* (*M*) on the numbers of nucleoli and the production of cytoplasmic inclusions by puromycin (*P*). All cultures were stained after 48 h of treatment indicated below the histogram, and nucleoli and inclusions were enumerated at this time. 1,000 mononucleate cells were counted in each culture, and duplicate cultures were used in each experiment. The values shown are arithmetical means from four separate experiments. The concentration of puromycin was 100 μg/ml., actinomycin 0·03 μg/ml., mitomycin 1 μg/ml. Comparison of the two histograms shows a similarity of nucleoli and inclusions in their response to inhibitors of nucleic acid metabolism

While this view of the origin of the inclusions cannot be accepted or denied on the basis of morphological appearances alone, experiments with inhibitors of nucleic acid synthesis show another point of similarity between the inclusions and nucleoli. Treatment of HeLa cells with a low dose (0·03 μg/ml.) of actinomycin *D* is known to interrupt synthesis of ribosomal RNA (ref. 11) and to result in the disappearance of nucleoli after treatment for 24–28 h (ref. 12). Nucleoli gradually reappear, however, if actinomycin is omitted from the medium[12]. Fig. 4 shows that puromycin treatment did not result in the appearance of cytoplasmic inclusions if the cells were pretreated with and maintained on actinomycin *D* (Merck, Sharp and Dohme, Rahway, New Jersey). The inclusions did appear if actinomycin was withdrawn, or if mitomycin *C* (Calbiochem., Los Angeles, California) was used in place of actinomycin. Mitomycin is an inhibitor of DNA metabolism, with little direct effect on RNA synthesis[13], and Fig. 4 indicates that its presence in the medium does not lead to a gross reduction in nucleolar number. This parallelism in the behaviour of nucleoli and inclusions in response to inhibitors of nucleic acid metabolism emphasizes their similarity.

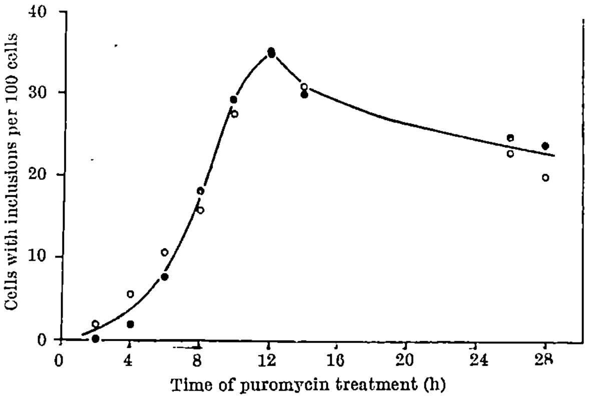

Fig. 2. Effect of duration of treatment on the production of cytoplasmic inclusions by 100 μg/ml. of puromycin. The values of two separate experiments are shown. ○, First experiment; ●, second experiment

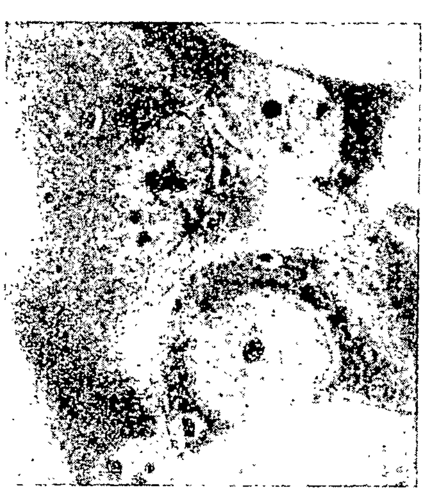

Fig. 3. HeLa cells stained by toluidine blue after 24 h of treatment with 100 μg/ml. of puromycin. Note the presence of multiple cytoplasmic inclusions (× 1,150)

IMMUNOLOGY

Contact Reactivity to Azo Dye Carcinogens

Old *et al.*[1], in a recent publication, have shown that while three carcinogenic polycyclic hydrocarbons (3-methylcholanthrene, 3,4-benzpyrene and 3,10-dimethyl-1,2-benzanthracene) were capable of eliciting contact hypersensitivity in guinea pigs, the non-carcinogenic anthracene and phenanthrene were devoid of a similar capacity. They proposed that there might be a correlation between the capacity of a substance to elicit contact sensitivity and its carcinogenic activity as both seem to depend on interaction with proteins of the host. Further, they have suggested that in guinea pigs, resistant to chemical carcinogenesis and highly susceptible to delayed hypersensitivity, the response takes the form of contact sensitivity; in the rat and the mouse prone to chemical carcinogenesis, but with little or no ability to acquire contact sensitivity, the end result is tumour formation.

If this view is correct, carcinogens other than the polycyclic hydrocarbons should be capable of eliciting delayed hypersensitivity in guinea pigs, while their non-carcinogenic analogues should be devoid of activity. Indeed a few azo dyes, some of which are powerful carcinogens in rats[2], have been shown to be allergenic in man[3,4] and in guinea pigs[5].

In the experiments reported here 6 carcinogenic and 7 non-carcinogenic azo dyes were tested in guinea pigs. Those which are carcinogenic in the rat did induce a high degree of cutaneous reactivity while 6 of the 7 non-carcinogens were devoid of sensitizing capacity. The exception was 2-methyl-4-dimethylaminoazobenzene, the only compound bound to rat liver proteins without being a carcinogen[6].

The azo dyes used in these experiments were: azobenzene, *p*-aminoazobenzene, 4-dimethylaminoazobenzene (DAB), and DAB substituted at different positions with a methyl, or fluoro or hydroxyl, or trifluoromethyl or with an amino group. Azobenzene was purchased from Matheson Coleman and Bell, *p*-aminoazobenzene from Eastman Chemicals: both compounds were of the highest grade purity. All the other highly purified dyes were a gift of Dr. J. A. Miller.

The animals used were adult albino guinea pigs of both sexes. They were sensitized once with a total of 0·4 mg of azo dye (0·1 ml. in each foot pad) dissolved in complete Freund's adjuvant and emulsified with saline. Skin testing was performed 3 weeks after sensitization. It consisted of applying to the shaved dorsal skin one drop of the azo dye used for sensitization, at a concentration of 1, 0·1, 0·01 and 0·001 per cent. Cross-reactivity to other azo dyes was tested at the same time; the test dose used was 1 per cent. Each test compound was dissolved in a mixture of 4 parts acetone and 1 part olive oil. Animals injected with adjuvant alone served as control. The reactions were recorded 24–36 h after testing and were graded from 0 to + + + + as to their severity.

Six of the 7 carcinogens used evoked strong reactions (2 to 4+) in all guinea pigs sensitized. All 28 animals injected gave a reaction to a test dose of 1 per cent; 24, 17 and 5 of the 28 animals reacted when tested with the sensitizer in a concentration of 0·1, 0·01 and 0·001 per cent respectively. The 7th carcinogenic dye (MAB) sensitized only 2 of 5 animals injected, and reactions were obtained to test doses not lower than 0·1 per cent. The cross-reactions were as strong as the homologous reaction and seemed to depend on the sensitivity of the animal rather than on the compound used for testing.

The results obtained on the allergenicity of azo dyes are compared with Miller's results[2] on the carcinogenicity of the same compounds in Table 1. As can be seen, there is a good correlation between sensitizing capacity in the guinea pig (column 4) and binding to rat liver proteins (column 3). This correlation holds for carcinogenicity except for 2 methyl DAB: this is the only non-carcinogenic azo dye which was found to be bound to rat liver proteins[2].

Although it is generally accepted that low molecular weight compounds have to combine with proteins in order to induce sensitization, it is not clear whether elicitation of a contact reaction in a sensitized animal can be brought about by the chemical alone, or only by the complete antigen. Eisen *et al.*[7], working with dinitrofluorobenzene (DNFB) and its analogues, distinguished between two classes of compounds: those which could, and those which could not, elicit a reaction in animals sensitized to DNFB. They were able to show that the 'elicitors' could combine with bovine γ-globulin *in vitro*, and with guinea pig skin proteins *in vivo*; the non-elicitors did not interact with protein either *in vitro* or *in vivo*. On the basis of these results they suggested that for a compound to elicit a reaction in a sensitized animal it must first combine with protein to do so. The azo dyes which were shown to be devoid of sensitizing capacity in the present series of experiments were shown not to combine with rat liver proteins *in vivo*[2] nor to interact with bovine serum albumin (BSA) *in vitro*[8]. Nevertheless, two of these dyes (4'NH$_2$DAB and 3'CF$_3$DAB) were capable of eliciting reactions in guinea pigs rendered sensitive to any of the seven sensitizers used (Table 1, column 5). This latter finding could be interpreted either by postulating that the two compounds, although they do not interact with rat liver proteins *in vivo*, nor with BSA *in vitro*, nevertheless combine with guinea pig skin proteins, or that some free azo dyes can elicit an allergic reaction. Assuming that 4'NH$_2$DAB and 3'CF$_3$DAB can combine with guinea pig skin proteins one would still have to explain their inability to sensitize.

Table 1. SENSITIZING CAPACITY AND CARCINOGENICITY OF AZO DYES

Azo dye*	Carcinogenic† index (rat)	Binding† to rat liver proteins	Capacity‡ to sensitize	Capacity to elicit skin reactions§
DAB	6	+	100 (4)	100 (9)
3'CH$_3$DAB	10–12	+	100 (5)	75 (4)
3'F DAB	10–12	+	100 (5)	66 (15)
4'CH$_3$DAB	< 1	+	100 (5)	73 (15)
4'F DAB	10–12	+	100 (5)	80 (15)
MAB	6	+	40 (5)	33 (15)
2 CH$_3$DAB	0	+	100 (4)	60 (5)
4'NH$_2$DAB	0	0	0 (5)	75 (8)
3'CF$_3$DAB	0	0	0 (5)	50 (20)
2 OH DAB	0	0	0 (5)	10 (20)
2'OH DAB	0	0	0 (5)	10 (20)
p-Aminoazobenzene	0	0	0 (5)	5 (20)
Azobenzene	0	0	0 (2)	0 (12)

* For formulæ see text.
† See ref. 2.
‡ The numbers refer to the percentage of animals sensitized; those in brackets indicate the numbers of animals in each experiment.
§ Cross-reactions: the numbers refer to the percentage of animals reacting; those in brackets indicate the number of sensitized animals skin tested.

The results reported here are in agreement with those of Old *et al.*[1]: there is a parallelism both in the case of the azo dyes and the polycyclic hydrocarbons between sensitizing capacity in guinea pigs, and carcinogenicity in rodents. Experiments are being carried out to find out whether suppression of immunological reactivity in the guinea pig or intensive immunization in the rat might not modify the patterns of response.

Immunological Distinction of *AKR* Thymocytes

In a previous communication we reported discovery of a strong antigen associated with the thymic lymphocytes of *AKR* mice[1]. Old, Boyse and Stockert have reported absorption of specific iso-antisera by thymus of *A* and *C*58 mice, and cytolysis of some leukæmias of *A* and *C57BL*/6 mice by the same iso-antisera. These results indicated presence of a common antigen (the *TL* antigen) in the tissues mentioned[2]. This antigen, and the antigens common to the Friend, Moloney and Rauscher viruses (the *FMR* antigens), are not related to the *AKR* thymic antigen[2,3].

In the present communication, a clear-cut serological differentiation between *AKR* lymphocytes of thymic and non-thymic origin is reported: thymic and splenic lymphocytes represent two antigenically different types of lymphocytes. The *AKR* thymic antigen is present to a high degree in brain and in some leukæmias of *AKR* mice, and to a lesser extent in other *AKR* tissues. The distribution of this antigen in thymocytes of other strains has been investigated. A preliminary report has been made[4].

Iso-antisera to tissues of *AKR* mice were prepared in *C3HeB*/*Fe* mice, that possess the same H-2 allele (H-2^{k} or H-$2^{k'}$) but presumably differ in other histocompatibility factors[5]; and in *C57BL*/6 mice, that possess the different H-2 allele H-2^{b} (ref. 6). The *AKR* tissues used were red blood cells, thymocytes, lymph nodes, spleen, marrow, liver; leukæmias *L*4946, *BW*5147, *S*775, and sarcoma *T*283. The resulting iso-antisera were titred by immune cytolysis[1,6,7] against the following *AKR* tissues: lymphocytes of thymic, lymph node, splenic and intraperitoneal origin, and marrow cells; leukæmias *L*4946, *BW*5147, *S*775; and against five different spontaneous leukæmias *RA*1 to *RA*5, which were transplanted intraperitoneally and tested within the first five transplant generations.

Absorptions of iso-antisera were carried out by a quantitative adaptation of the method of Möller[8]. Either a known number of viable cells, or a packed residue derived from a homogenate of a known wet weight of tissue, were used for absorption. The supernatant was titred by immune cytolysis against the same tissue as was used for preparation of the iso-antisera.

The cytolysis data are presented in abbreviated form (Table 1). All *C3HeB*/*Fe* iso-antisera cytolysed *AKR* thymocytes, while none cytolysed other types of normal lymphocytes (Table 1*A*). This represents clear-cut evidence of the antigenic distinction between *AKR* thymocytes and other normal *AKR* lymphocytes. Five out of eight *AKR* leukæmias tested (such as *RA*3) were highly sensitive to *C3HeB*/*Fe* iso-antisera, while three (such as *L*4946 and *RA*1) were not. This indicates that the five leukæmias sensitive to these iso-antisera are antigenically related to thymocytes (Table 1*A*).

In contrast, *C57BL*/6 iso-antisera showed a variety of reactions (Table 1*B*): *C57BL*/6 iso-antiserum against spleen gave strong cytolysis of spleen cells but very weak cytolysis of thymocytes. The iso-antiserum against thymocytes gave strong cytolysis both of thymocytes and of spleen cells. The relative potencies of iso-antisera involved in these reactions give evidence of wide quantitative differences in the surface antigens of thymocytes and of other normal lymphocytes. Marrow cells were resistant to all iso-antisera that were tested. Cytolysis of *AKR* leukæmias by the same iso-antisera showed that certain leukæmias reacted similarly to one or other of the normal cell types. For example, *L*4946 leukæmia reacted similarly to splenic lymphocytes (Table 1*B*).

Table 1. Cytolysis of Normal and Leukæmic *AKR* Cells by *C3HeB*/*Fe* and *C57BL*/6 Iso-antisera

	Potency* for cytolysis of					
	Normal *AKR* cells			*AKR* leukæmias		
	Thymus	Spleen	Marrow	*L*4946	*RA*1	*RA*3
(*A*) Iso-antisera prepared in *C3HeB*/*Fe* mice against *AKR*						
Thymus	450	< 2	< 2	(39% a.c.)†	< 2	96
Spleen	524	< 2	< 2	(10% a.c.)	< 2	97
*L*4946	340	< 2	< 2	(46% a.c.)	< 2	65
(*B*) Iso-antisera prepared in *C57BL*/6 mice against *AKR*						
Thymus	450	82	< 2	24	1·8	18·1
Spleen	1·6	710	(21% a.c.)	218	19·4	74
*L*4946	4	112	(21% a.c.)	78	5·4	14·2

* Potency is expressed as 100/cytolytic titre, where the cytolytic titre is the final concentration of iso-antiserum (per cent) that gives 50 per cent cytolysis

† The highest cytolysis obtained was 39 per cent above the control level.

Absorption experiments further substantiated the results of the cytolysis data. Absorption of a *C3HeB*/*Fe* iso-antiserum prepared against *AKR* thymocytes, by normal lymphocytes other than thymocytes, was low or negligible, except for adult splenic lymphocytes, which absorbed 5 per cent of the iso-antibody absorbed by the same number of *AKR* thymocytes. The *AKR* leukæmias which behaved similarly to splenic lymphocytes in cytolysis experiments absorbed between 4 and 14 per cent, while leukæmias which behaved similarly to thymocytes (Table 1) absorbed 39–95 per cent of the iso-antibody, calculated on the same basis. These results suggest that spontaneous *AKR* leukæmias fall into two types, those with and those without a high content of the *AKR* thymic antigen.

Residues of homogenates of various normal *AKR* tissues were tested for absorption of the *C3HeB*/*Fe* iso-antiserum against *AKR* thymocytes. Brain absorbed as much iso-antiserum as thymus, while appendix and lung absorbed approximately one-fortieth as much. Absorption by liver, skeletal muscle, kidney and testis was less than 1 per cent of that of *AKR* thymic residue derived from the same wet weight of tissue. These data do not indicate whether the *AKR* antigen is present on cells of spleen, appendix and lung, or whether presence of the antigen is due to migration of thymocytes to these tissues. However, the content of the antigen was far too high in brain to be ascribed to the presence of thymocytes.

Thymocytes of *RF* mice and of neonatal *AKR* mice were cytolysed by the *C3HeB*/*Fe* antiserum to *AKR* thymocytes at the same potencies as the homologous *AKR* cells, and the amount of iso-antibody absorbed by these cell types was only slightly lower. In contrast, thymocytes from *C3HeB*/*Fe*, *C3H*/*DiSn*, *C3H*/*St*, *A*, *A*/*He*, *BALB*/*c*, *C57BL*/6, *C57BL*/10, *C57L*, *C*58, *DBA*/1, *DBA*/2, *SWR* and 129 mice were not cytolysed, and did not absorb detectable amounts of iso-antibody. Comparison of these data with Table 10 of ref. 5 indicates that the *AKR* thymic antigen is not associated with any of the six known mouse histocompatibility factors *H*-1 to *H*-6.

An *AKR* iso-antiserum to *C3HeB*/*Fe* thymocytes cytolysed thymocytes from all the mouse strains mentioned here, except strains *AKR* and *RF*. These data exclude an association between the *C3HeB*/*Fe* thymic antigen and any of the six known mouse histocompatibility factors *H*-1 to *H*-6 (ref. 5). Quantitative absorption experiments showed that the tissue distribution of the *C3HeB*/*Fe* thymic antigen was similar to that of the *AKR* thymic antigen.

It is unlikely that either the present *AKR* or *C3HeB*/*Fe* thymic antigens are related to the *X* antigens of Gorer *et al.*, since *EL* leukæmias bearing the *X* antigens could not be cytolysed by iso-antibody[9]. Not only the *AKR* thymic antigen, but also the *C3HeB*/*Fe* thymic antigen, appears to be distinct from the *LT* antigen: *C57BL*/6 thymus, which possesses the *C3HeB*/*Fe* antigen, failed to absorb iso-antibody directed against the *LT* antigen[2]. In line with the suggestion of Amos[5] that apparently new serologically determined antigens be first designated by Greek letters, the names θ-*AKR* and θ-*C3HeB*/*Fe* are proposed for the two thymic antigens described in this investigation. The present results will be published elsewhere in detail.

RADIOBIOLOGY

Shortening of the Span of Life of Rats by 'Myleran'

THERE are few reports on late somatic effects of radiomimetic chemicals, especially those dealing with span of life. In mice and rats the first observations on the effects of single and repeated doses of nitrogen mustards and myleran on span of life are rather conflicting and the dose-response relationship has not been established[1–5]. Following the administration of single doses of a radiomimetic agent the span of life shortening is less effective because the sub-lethal dose range of many of them is narrow. By repeated doses properly spaced to avoid the early mortality, a larger total dose may be administered and in this way a significant reduction of span of life obtained[3]; however, as more variables are introduced inherent to dose fractionation, the interpretation of the dose-response relationship may be complicated. On the other hand, the early mortality in rats associated with bone marrow aplasia induced by single doses of myleran can be successfully reduced by isologous and homologous bone marrow transfusions, and in those rats which survive 30 days the observation of long-term effects can be extended to single doses of myleran two or three times greater than the $LD_{50/30}$ (refs. 6, 7).

This communication reports the relationship between the reduction of span of life in rats and the dose of myleran. White male *L*-strain rats bred here by random mating were used; at the start of the experiment they were 3–4 months old, weighing 140–150 g. A group of rats survived the first 30 days to mid-lethal doses of myleran (12·1, 13·8 and 15·5 mg/kg). Another group is composed of 30-day survivors treated with bone marrow transfusions (32–128 × 10^6 nucleated cells on the 1st, 3rd or 5th day) following administration of increasing doses of myleran (from 15·5 to 48·3 mg/kg). A previous report from this laboratory described experimental methods and results on the 30-day survival[6]. The mean span of life and other criteria of longevity were established from the day of administration of myleran. Simultaneously until natural death a group of normal rats which served as controls has been recorded. Routine autopsies were performed on all animals.

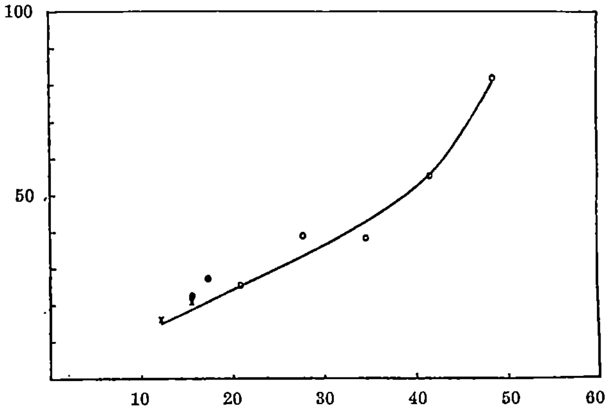

Fig. 1. The relationship between the shortening of span of life of *L*-strain rats and the dose of myleran. ×, rats receiving only myleran; ○, rats treated with bone marrow transfusions after myleran administration; ●, rats treated with bone marrow transfusions, data corrected for the mortality occurring during the 2nd and 3rd month

The results are summarized in Table 1. The mean, median and maximal spans of life at various dose-levels indicate that the long-term survival of rats is inversely related to the dose of myleran.

In the group of rats not treated with bone marrow transfusions, however, observed values for the mean span of life are not significantly different from control values. To demonstrate that the observed differences are statistically significant a greater number of animals had to be used and this fact emphasizes why definitive data at sub-lethal and mid-lethal dose ranges are difficult to obtain[4].

In the group of rats treated with bone marrow transfusions following myleran doses of 15·5 and 17·2 mg/kg the rats presented on the whole a more important reduction of span of life not in relation to dose of myleran used. Among them about 25 per cent died during the second and third month with symptoms indicating a secondary rejection of the bone marrow graft. This particular incidence of mortality does not occur among the rats which received nearest myleran doses without bone marrow treatment or in bone marrow treated rats following administration of higher myleran doses which depress more profoundly the immunological defence reactions of the host. By excepting the latter two dose-levels, the lowest myleran dose that resulted in a statistically significant decrease in span of life was 20·7 mg/kg, at the 0·01 confidence-level.

In Fig. 1, the shortening of life in rats expressed as a percentage of the normal span of life has been plotted against the doses of myleran on the ordinary scales. If

Table 1. LONGEVITY DATA OF *L*-STRAIN RATS SURVIVING 30 DAYS FOLLOWING ADMINISTRATION OF SINGLE DOSES OF MYLERAN WITH OR WITHOUT BONE MARROW TRANSFUSIONS

Experimental conditions	Dose of myleran (mg/kg)	No. of rats	Mean span of life ± *E.S.* (days)	Reduction of mean span of life (%)	Median span of life (days)	Maximum span of life (days)
Controls	—	24	551 ± 41	—	558	998
Myleran	12·1	21	461 ± 34	16·3	482	774
	13·8	12	482 ± 65	12·5	499	789
	15·5	13	436 ± 64	20·9	449	719
Myleran and bone marrow	15·5	106	324 ± 22 (427)*	41·2 (22·5)*	337	852
	17·2	75	303 ± 25 (401)*	45·0 (27·2)*	298	778
	20·7	99	410 ± 21	25·6	442	880
	27·6	119	336 ± 16	39·0	333	700
	34·5	80	340 ± 20	38·3	333	766
	41·4	29	246 ± 33	55·4	250	581
	48·3	2	99	82·0	99	128

* Corrected for the mortality occurring during the 2nd and 3rd month.

we assume that transplantation of bone marrow in rats is ineffective to reduce shortening of span of life, as it has been found in irradiated animals[8], the shortening of span of life by myleran is a non-linear function of the dose with an important reduction of span of life with the increasing dose. It is interesting that a similar dose-response relationship was found in animals exposed to single doses of whole body irradiation[9].

When compared in terms of the $LD_{50/30}$ doses, the ionizing radiation appears a more potent agent for reducing the span of life than myleran. However, the comparison on this basis may be misleading because the sensitivity of rat bone marrow tissue to myleran may be more important than to ionizing radiation and also relatively to the sensitivity of other tissues which could be involved in the shortening of span of life. For example, the sensitivity of bone marrow tissue to myleran, as reflected by the $LD_{50/30}$ doses, is more important in rats than in mice (respectively 14 and 56·7 mg/kg)[6]. If there are no species differences for the shortening of span of life by myleran, it can be predicted that single sub-lethal doses above 20·7 mg/kg of myleran would significantly reduce the span of life in mice.

In addition, routine autopsies of rats showed the presence of lens cataracts and testis atrophies with incidence rate and degree in proportion to myleran dose. The incidence of macroscopic neoplasms was not above the normal level observed in the strain of rats used. Terminal causes of death apparently did not differ from those found in normal controls dying spontaneously; but it is not impossible that systematic histological investigations now in progress would disclose other particular findings, especially in rats which received higher doses of myleran.

It may be concluded that single doses of radiomimetic chemicals share with ionizing radiations the property to reduce the span of life in mammals. It is hoped that further investigations in this field may shed more light on the mechanism of shortening of life by the agents described here and on factors which could modify their delayed somatic effects.

This work was supported by grants from the Home Office (Ministère de l'Intérieur) of Belgium. The myleran (1 : 4 dimethanesulphonyloxybutane—trade name 'Myleran') used in this work was kindly supplied by Burroughs Wellcome and Co. Laboratories, London.

Distribution and Fate of Soluble Proteins labelled with Iodine-131 from Rat and Rabbit Livers

Soluble proteins of rat and rabbit liver have been labelled[1] with iodine-131 using the chloramine *T* radio-iodination procedure[2,3]. In this communication the distribution and fate of liver ^{131}I-proteins in relation to the chloramine *T* and iodine monochloride[4] (ICl) procedures are described.

Soluble proteins were extracted from rat and rabbit liver, were dialysed and labelled with carrier-free iodine-131 ('*IBS*.3', Radiochemical Centre, Amersham) as previously described[1]. ^{131}I-tungstophosphoric acid (TPA, final concentration: 1·7 per cent in 0·68 N hydrochloric acid) soluble radioactivity as percentage of the original radioactivity was measured with carriers sodium iodide and bovine serum proteins.

The distribution of homologous liver ^{131}I-proteins was investigated in male Wistar rats of about 250 g weight having fasted for 26 h. The sample (100–120 μc.) was injected via the femoral vein into the ether-anæsthetized animal and its total body radioactivity was immediately counted. After a 15-min interval blood was withdrawn from the abdominal aorta and perfusion with 1 l. heparinized saline was started via the portal vein. Afterwards several organs were removed, enclosed in thin polythene bags and separately set, in their proper position, inside the thoracic and abdominal cavity of a non-radioactive rat carcass. In identical geometry, the rat was counted in order to assess the percentage of dose retained by the organs. The radioactive rat carcass and an aliquot of blood were also measured.

Results are shown in Table 1. A somewhat lower yield of protein-bound radioactivity was observed using higher amounts of iodine-131 (4 mc.). Raising the amount of chloramine *T* (5–20 mg) determined, after addition of the reducing agent, the appearance of an increasingly intense opalescence in the protein solution. Correspondingly an approximate proportionality between the percentage of dose retained by the liver and the amount of chloramine *T* used became evident, the higher uptake being due to some denatured proteins during the iodination. Heat-denatured[5] serum and liver ^{131}I-proteins gave 81 and 89 per cent retention, whereas normal serum ^{131}I-proteins gave about 1·2 per cent[3].

When liver proteins were labelled with iodine-131 by using the iodine monochloride method[4] (the final reagent

Table 1. Rat Liver Retention of Rat Liver Soluble ^{131}I-Proteins

Labelling techniques	Percentage total ^{131}I-recovery	Percentage of dose after 15 min from injection in: Blood	Liver	Carcass
Chloramine *T* (2 mg)	28·0	22·9 ± 1·3	51·5 ± 0·3	16·7 ± 0·8
Chloramine *T* (5 mg)	40·6	15·5 ± 0·5	61·4 ± 0·9 (+19·2%)	14·7 ± 0·2
Chloramine *T* (10 mg)	44·0	13·4 ± 2·4	66·7 ± 0·3 (+29·5%)	12·7 ± 1·1
Chloramine *T* (20 mg)	43·2	6·8 ± 0·2	74·7 ± 0·2 (+45·0%)	11·1 ± 0·7
Chloramine *T** (20 mg)	43·2	9·3	68·5 (+33·0%)	11·6
Iodine monochloride (126 μg)	4·5	22·1	51·9 (+0·8%)	17·9
Iodine monochloride (210 μg)	6·8	21·9	52·7 (+2·3%)	16·7

Each sample of liver proteins (29·4 mg) was labelled with 4 mc. iodine-131. Percentages of ^{131}I-TPA soluble radioactivity ranged between 3·5 and 6·7 per cent. Carrier liver proteins were added to prevent self-irradiation. About 10 mg of liver ^{131}I-proteins (in 2·0 ml. *p*H 7·6 phosphate buffer) were administered to the rats except one. Figures with ± *S.E.* represent mean of 3 animals. Figures between brackets represent percentages of higher liver retention.

* This rat received 59 mg liver proteins.

Percentage of dose in liver: *P* (2 mg : 5 mg) < 0·001; *P* (2 mg : 10 mg) < 0·001; *P* (2 mg : 20 mg) < 0·001.

Table 2. Rabbit Liver Soluble ^{131}I-Protein Recoveries using the Iodine Monochloride and Chloramine *T* Radioiodination Procedures

Labelling techniques	Opalescence of protein solutions	Percentages ^{131}I-recovery	^{131}I-TPA soluble radioactivity
Iodine monochloride			
126 μg	–	12·1	6·3
210 μg (*a*)	–	18·3	4·9
Chloramine *T* 2 mg (*b*)	–	43·8	5·8
Chloramine *T* 5 mg (*c*)	+	45·9	3·7
Chloramine *T* 10 mg (*d*)	+ +	48·5	3·5

The reaction mixture was made up with proteins (30·9 mg) in 0·15 M phosphate buffer, *p*H 7·6, with 5 mc. iodine-131 per each sample. Addition of carrier liver proteins prevented self-irradiation damage. Percentages of ^{131}I-TPA soluble radioactivity were estimated on the eluates.

a, *b*, *c*, and *d* refer to curves shown in Fig. 1.

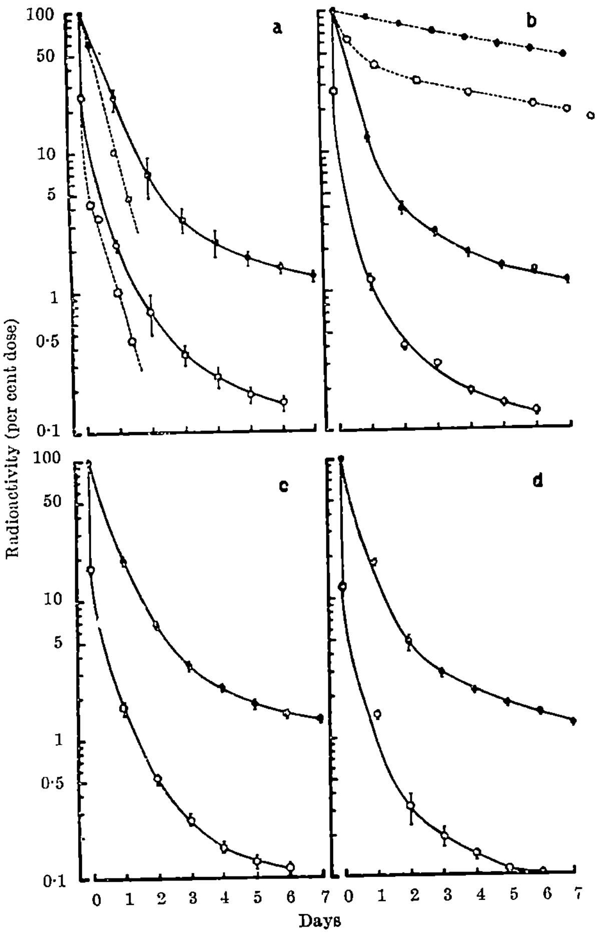

Fig. 1. Behaviour of soluble proteins extracted from rabbit liver and labelled with iodine-131 by the (*a*) iodine monochloride (210 μg) and chloramine *T*; (*b*) 2 mg; (*c*) 5 mg and (*d*) 10 mg, procedures and injected into rabbits. Labelling efficiencies of these samples are reported in Table 2. Vertical bars represent ± *S.E.M.* of 2 observations; ●, total body activity; ○, plasma activity as per cent of value at injection time. Dotted curves represent the behaviour in (*a*) of ^{131}I-sodium iodide, and in (*b*) of homologous normal serum ^{131}I-proteins

contained 0·42 mg of iodine as monochloride per ml.) 52 per cent ^{131}I-proteins were taken up by the liver, and this value is close to that obtained by using ^{131}I-proteins kept in contact with only 2 mg chloramine *T*.

Published reports[6] indicate that the *in vivo* behaviour of serum ^{131}I-proteins labelled by the ICl method is almost identical with that of the corresponding biosynthetically labelled ^{14}C-proteins.

Another test consisted of following (Fig. 1), in rabbits, the total body radioactivity and the intravascular (μc./ml. of plasma) radioactivity (all results being expressed as a percentage of the injected dose) of rabbit liver ^{131}I-protein samples (Table 2). Male rabbits, weighing about 2·75 kg, were used throughout and were separately housed in metabolism cages. In order to increase the rate of iodide excretion the drinking water contained 0·00034 M sodium iodide and 0·08 M sodium chloride for 15 days before and up to the end of the experiment. The liver ^{131}I-protein sample (about 500 μc. in 3·0 ml.) was injected into the marginal ear vein, and about 0·5 ml. of blood withdrawn 9 min later from the opposite ear vein. The activity to be injected and the syringe washings were counted and the injected dose obtained by difference. Plasma volume per each rabbit was measured[7] two weeks before by the injection of about 2 μc. rabbit ^{131}I-albumin. Thus by knowing the plasma volume and the dose the 100 per cent value (plasma activity) at injection time could be calculated. Total body and plasma radioactivities were measured as already described[3].

Curves were very complex as liver proteins are a heterogeneous mixture[8]. Fig. 1 shows that ^{131}I-proteins disappeared very rapidly from the circulation and that the clearing was even faster if, during iodination, 5-10 mg chloramine *T* were used. The slower fall of total body radioactivity was due, at least in part, to the diffusion into the extravascular fluid of free radioactivity liberated for the intense protein breakdown. Total body and plasma radioactivities half-lives for ^{131}I-sodium iodide (*a*) and serum ^{131}I-proteins (*b*) were shorter and much longer respectively.

Vertical starch-gel electrophoresis was performed according to Smithies[9] with a discontinuous buffer system[10] and a contact autoradiogram was taken with X-ray film on the bottom slice of the gel. It was noted that when chloramine *T* amounts were higher more ^{131}I-proteins remained near to or at the origin. The sieving effect of the gel on a modified protein molecular size, as suggested by the appearance of opalescence, might explain the result.

It is concluded that the reagents used in the radioiodination procedure, if not used under carefully selected conditions, can adversely modify the biological properties of liver ^{131}I-proteins whereas little, if any, protein damage might derive from either substitution of iodine-131 or from self-irradiation[11].

Recovery from X-ray Injury and the Effect of Oxygen

Observations were reported recently[1,2] on a significant reduction of the extrapolation number of the survival curves of mammalian cell cultures which were exposed *in vitro* to varying X-ray doses under anoxic, as contrasted to aerobic, conditions. In view of the relationship between the extrapolation number and the extent of recovery from radiation damage, noted in connexion with treatment by fractionated doses of X-rays[3,4], fractionated treatment of anoxic cells can be expected to lead to a decrease or lack of recovery. This communication records the results of some preliminary experiments designed to test this possibility. Since access to oxygen is to a great extent reduced in neoplastic cell populations *in vivo*[5], the data should further clarify some of the factors which determine the result of tumour radiation therapy, as commonly practised according to various dose-fractionation schedules.

In vitro cultures of the *ELT* sub-line of *ELD*, an Ehrlich ascites tumour, were used as the cellular material[2,6,7]. In each test, a series of nine 'Pyrex' Petri dishes 6 cm in diameter, containing 4–6 ml. nutrient solution[2], were implanted with different dilutions of a suspension of single cells. This was prepared by trypsin treatment of cultures growing in a non-confluent monolayer. After 3 h incubation at 38° C in a moist atmosphere of carbon dioxide in air, the lids of the dishes were removed and the medium withdrawn to such an extent that a fluid

layer of only about 1 mm was left to cover the cells which were now firmly attached to the bottom of the vessels. Afterwards, six dishes were exposed to X-rays and the remaining three dishes used as unirradiated controls, subjected to the same procedures as the irradiated ones. Half the cultures exposed to radiation received a dose of either 200 r. or 600 r., while the other half was treated with the corresponding double dose. After exposure, the dishes were refilled with fresh medium and reincubated for a period of 18 h. The cultures irradiated with 200 r. or 600 r. were then exposed to a repeated treatment with the same X-ray dose which they had received, while the other cultures were subjected to sham-irradiation. Afterwards the dishes were incubated for 10 days with medium changes taking place at 3–4 days intervals. Clones, fixed and stained *in situ*, comprising more than fifty cells were then counted. The fraction of cells surviving irradiation with retained capacity for reproduction, as judged by their clone forming capacity, was used as the measure of the radiation effect, and was calculated as the percentage of unirradiated controls of the same experiment.

The dishes were exposed to X-rays at room temperature in an air-tight plastic chamber. For 20 min prior to, and during, irradiation, the chamber was gassed with humidified oxygen or argon, both containing carbon dioxide to maintain a *p*H of 7·0–7·2 in the medium. The oxygen contamination of argon was less than 3 p.p.m. Radiation was generated at 190 kV and 15 m.amp. Details of the gassing system and the radiation procedure have been described previously[2].

The mean surviving fraction of cultures exposed in argon or oxygen to either a single dose of X-rays, or to irradiation with the same dose split into two equal parts, is presented together with standard errors in col. 7, Table 1. It can be seen that the size of the mean surviving fraction after a single exposure to a certain dose agrees closely with the value (col. 8) calculated from the regression data of the survival of *ELT* after irradiation under comparable atmospheric conditions[2]. The difference between the surviving fractions after the single and the fractionated irradiation with the same dose has been calculated in each of the tests separately. The mean of the differences and the corresponding standard errors are presented in col. 9. Fractionation led to minor and statistically insignificant differences only, when compared with the effect of single exposure in an anaerobic environment. In the presence of oxygen there was a clear differential effect, however. Single exposure was about three times more efficient in damaging the reproductive integrity of cells than fractionated treatment. The difference was statistically significant ($P < 0{\cdot}001$).

The increased survival due to fractionated irradiation under aerobic conditions suggests that a certain repair of the radiation damage occurs during the time interval which elapses between the treatments. Evidence presented by Elkind *et al.*[3] supports the view that such repair concerns the sub-lethal damage which is accumulated before a cell is lethally affected, and which has an expression in an extrapolation number of the survival curve larger than unity. The ratio of survival, following two exposures, compared with a single equivalent dose, was found[3] to have a value which is close to that of the extrapolation number if the length of the fractionation interval exceeds 15 h. This observation is in agreement with the result reported here, since the extrapolation number of the survival curve of *ELT* after aerobic irradiation has previously been found[2] to be about 2, that is, close to the survival ratio of 3 as calculated from the present results.

The lack of any difference in response due to dose fractionation in an anaerobic environment can be taken to indicate an absence of repair processes as regards cellular reproduction. After anoxic irradiation[2], the survival of *ELT* exhibited a nearly exponential dose-effect relationship with an extrapolation number close to unity. The present data support the postulate[3] that, under such conditions, the ratio of the surviving fractions, after a single, compared to fractionated, irradiation, will also nearly equal unity. Thus, the effect of anoxic treatment by sparsely ionizing X-rays resembles closely the effect of densely ionizing radiations, also characterized by an exponential survival pattern of cells without the involvement of any recovery phenomenon on dose fractionation[8]. Our result agrees with observations concerning the effect of fractionated gamma irradiation on *Trifolium repens* in the presence or absence of oxygen[9]. It is, however, at variance with findings made with human kidney cells in similar experiments[10]. The disagreement may be explained by the oxygen contamination of the nitrogen, used in the anaerobic assays, stated[10] to be about 0·1 per cent. Such an oxygen concentration has been shown to be sufficient to raise the radiosensitivity of bacterial cultures to half the maximal oxygen enhancement[11].

In summary, the results presented show a differential effect of fractionated irradiation with regard to the recovery phenomenon of the cells, depending on the presence or absence of oxygen during treatment. Considering the generally impaired oxygen supply of neoplasms as contrasted to their surroundings, it is thus conceivable that normal tissues, though enhanced in sensitivity, may nevertheless recover from radiation damage to a comparatively larger extent than neoplastic tissue in the course of fractionated X-ray therapy. Our result supports the view[12] that, in contrast to the idea of a purely quantitative dose-modifying influence of oxygen, there is also a qualitative difference in the lethal cellular damage caused by irradiation with X-rays under aerobic as compared with anoxic conditions.

Effect of Alkylating Agents and Whole-body X-irradiation on Thymus

MANY investigations have indicated the disruption of the structure of DNA or nucleohistone by nitrogen mustards or ionizing irradiation[1,2]. The labilization of nucleohistone from thymus after irradiation has been measured by Hagen[3] by increased extraction of DNA by phenol treatment. Cole and Ellis[4] have reported an increase in soluble polynucleotide in spleen after irradiation. In investigations on the effects of these agents on amino-acid incorporation in thymus nuclei and cytoplasmic microsomal and 5·1*P* fractions[5], the presence of acid insoluble DNA material in the various fractions became apparent. The finding is reported primarily because of its importance in interpreting results of changes in enzyme activities in cell fractions from radio-sensitive tissues after treatment.

In investigations on effects of whole-body X-irradiation, 10–12-week-old male rabbits were exposed to 650 r., 260-kV radiation. 'Mustargen' (methyl-*bis*[β-chloroethyl]amine hydrochloride), dissolved in 0·04 M sodium phosphate buffer, *p*H 7·4, was injected through the ear vein (4 mg/kg body-wt.). Thymuses from 4–5 animals were pooled in each experimental group. Rabbit thymus nuclei and cytoplasmic fraction were made by slow stirring in 0·25 M sucrose–0·0033 M calcium chloride based on the procedure of Allfrey, Mirsky and Osawa[6]. The cytoplasmic fraction was centrifuged at 15,000*g* for 15 min. The microsomal fraction was prepared from the resulting supernatant by centrifugation for 1 h at 105,000*g*. The 5·1*P* fraction was prepared from this supernatant by the commonly used procedure.

The fractions were precipitated and washed with cold 4 per cent perchloric acid, alcohol and ether to obtain protein–nucleic acid powders for analysis. DNA content was determined using Webb's method[7]. The molecular status of the DNA material in these fractions is not known at the present time and is under investigation.

Results in Table 1 illustrate the presence of DNA in the microsomal fraction and 5·1*P* fraction at varying times after whole-body X-irradiation. DNA is present in both fractions 2 h post-irradiation. No DNA was found at 1 h, which would agree with the observation of Hagen[3] of a 1-h lag before a measurable change in phenol extraction of DNA from thymus. The amount of DNA in the fractions increases up to 6 h after irradiation. By 18 h the DNA content is decreased, probably due to the action of DNase and the phagocytic activity, which are known to be increased at this time after irradiation.

Table 1. EFFECT OF X-IRRADIATION ON DNA CONTENT OF ISOLATED THYMUS CYTOPLASMIC FRACTIONS
(Expressed as percentage dry weight of dry protein–nuclei acid residue)

	Hours after irradiation						
Fraction	0	1	2	3	4	6	18
Microsomal	0·96	0·90	2·3	4·6	9·4	15	3·4
5·1*P*	0·6	0·67	1·4	5·2	11	11	4·7

Similar observations (Table 2) are noted after treatment of rabbits with the nitrogen mustard, 'Mustargen'. Thus one early manifestation of the effect of both these agents on thymocytes is a labilization of the structure of the nuclei and the nucleohistone.

Table 2. EFFECT OF MUSTARGEN ON DNA CONTENT OF ISOLATED THYMUS CYTOPLASMIC FRACTIONS
(Expressed as percentage dry weight of dry protein–nucleic acid residue)

	Hours after injection					
Fraction	0	4	6	8	12	18
Microsomal	0·86	2·0	7·1	13·2	20·4	2·1
5·1*P*	0·84	1·2	5·0	12·4	14·5	5·5

These investigations do not permit the conclusion that the initial site of action of ionizing radiation or alkylating agents is directly on the structure of the nucleohistone. The observations reported here could be the result of disaggregation of chromatin because of loss of ions or proteins required for structure; this, in turn, could be caused by direct action of the agents or changes in nuclear membrane permeability[8]. It is also possible that the disruption of nucleohistone structure could be a primary effect. Peacocke and Preston[9] have measured the release of histone from nucleohistone in solution by γ-irradiation with no denaturation of the DNA. An initial change in the structure of the nucleohistone could make the DNA susceptible to the action of DNase, and it is the products in various stages of degradation which appear in the isolated cell fractions. Brookes and Lawley have studied the alkylation and subsequent change in structure of DNA[10]. Biesele[11] has discussed the effects of alkylation and emphasized that alkylations of RNA and protein may also be significant.

Regardless of mechanism, the gross observation reported here of the presence of nuclear products in cytoplasmic fractions at early times after treatment with these agents indicates that disruption of damaged nuclei must be considered in interpreting changes in enzyme activities in all cell fractions. It is also obvious that the presence of DNA breakdown products in the cell fractions must be considered in evaluating data on effects on various aspects of nucleic acid metabolism.

My results also indicate that the DNA material is removed from the microsomal fraction by the deoxycholate treatment in preparation of the ribosomal fraction. Data on incorporation of amino-acid by intact nuclei and the microsomal, ribosomal fractions, to be published in detail elsewhere, indicate that, at early times after X-irradiation or 'Mustargen' treatment when *in vitro* amino-acid incorporation by nuclei is inhibited, incorporation by the ribonucleoprotein particles in the ribosomal fraction is not inhibited.

BIOLOGY

Responses of a New Hibernator (*Citellus variegatus*) to Controlled Environments

THE phenomena of hibernation and æstivation have both been recorded in the genus *Citellus*, and although it is not known whether the two phenomena are physiologically the same[1], nevertheless hibernation seems to be an adaptation to an unfavourable cold seasonal environment, and æstivation an adaptation to an arid hot environment with seasonal drought. It is of interest, therefore, to find that the rock ground squirrel, *Citellus variegatus*, the habitat of which is the arid south-west from Utah to southern Mexico[2], is capable of hibernating but does not appear to æstivate. Hibernation as used here refers to a mammal with a homothermic temperature of approximately 37° C, but which is able to lower this temperature to the environment and raise it again against the gradient.

In early June 1963, twelve animals of this species were trapped 10 miles west of Las Vegas, Nevada. They comprised seven adults and five juveniles. All survived well in captivity, and gained weight rapidly, the adults becoming extremely obese.

On August 5, one month after capture, groups of two animals were exposed to 3° C and 23° C environmental temperatures, with food ('Purina Chow') and water *ad libitum*, to determine whether spontaneous æstivation occurred as in *Citellus mohavensis*[3]. On August 15 two more groups of two were exposed to the same environmental temperatures, but only food was supplied. In the groups with food and water *ad libitum* no evidence of spontaneous æstivation was observed, and at the time of writing (December 1963) no evidence of spontaneous hibernation has been observed either. The latter is in contrast to *Citellus mohavensis* which æstivates and hibernates spontaneously[3] and *Citellus lateralis* which hibernates spontaneously[4]. The groups with food but no water lost weight gradually, but no drop in body temperature was observed in those in an environment of 3° C for 45 days when water was given, or the animals died. In those at 23° C there was no observed drop in body temperature for 50 days, but thereafter one animal did appear to become hypothermic on occasions for a few hours, body temperatures of 28° C and 31° C being recorded. During October food was denied to four more animals at an environment of 3° C, and in all cases they hibernated within 10 days. However, under these conditions the body temperature does not apparently fall to the environment like that of other hibernators[3,5] but is maintained at a low of 8° C in a 3° C environment. It seems that *C. variegatus* has some form of 'thermostat' set considerably above 0° C, which is confirmed by the fact that an animal in an environment of −18° C continues to hibernate successfully, but the body temperature is held at 8–10° C. The œsophageal temperature is slightly above the rectal.

This species also has a remarkable tolerance to dehydration. When free water is denied but food ('Purina Chow') permitted, the animals slowly lose weight, but some have survived more than 100 days at 23° C with no appreciable drop in body temperature. *C. lateralis* at the same season (that is, active one) will only survive some 20 days with no free water (Pengelley, unpublished results), but the percentage loss in weight before death is about 70 per cent in both species. There are, no doubt, differences in physiological adaptations to water deprivation in two such species (now being investigated), but there is an obvious behavioural difference. *C. lateralis* becomes highly active within 24 h of deprivation of water, whereas *C. variegatus* gives no response that can be observed and remains comparatively docile. Although the environmental conditions are probably not identical[6,7], *C. variegatus* may prove to have the longest survival time of any mammal yet examined which is unable to maintain body weight without free water (*Dipidomys merriami* can[6]); this is, of course, provided there is no lowering of body temperature in response to water deprivation.

The experimental results indicate that in *C. variegatus* the stimulus for entrance into hibernation is lack of available food, that æstivation does not occur spontaneously or in response to lack of water, and that while the animal is able successfully to lower its body temperature and raise it against the gradient, it does not in fact permit it to fall below 8° C. Thus, its behaviour is quite different from other species within the genus. Furthermore, it is possible to reason that the evolutionary adaptations to this animal's arid habitat are high tolerance to water deprivation during summer (the dry season throughout most of its range), and the ability to hibernate during winter in response to scarcity of food which it does not store, at least in captivity.

This work was supported in part by grant *G* 19295 from the U.S. National Science Foundation and grant 50 from the Kaiser Foundation. I thank Dr. James Deacon, University of Nevada, Las Vegas, for assistance in obtaining the animals.

Liver Mitotic Rates and Weights in Young, Rapidly Growing Rats after Serum Injection

THE systems which seemingly demonstrate control of cell division in rat liver commonly involve change in the composition of the blood. For example, Stich and Florian[1] found that single injections of normal serum administered to partially hepatectomized rats inhibited mitosis, while serum from rats which had been partially hepatectomized stimulated mitosis following a single injection. Recently, Moya[2] reported that single injections of both normal and post-hepatectomy serum prepared from arterial blood inhibited mitosis in regenerating livers. Moreover, Smythe and Moore[3] reported that weights of regenerating livers were decreased by repeated injections of normal plasma. These results, obtained in adult rats, raise the question of whether treatment with serum injections has the same effects on livers of young, rapidly growing rats.

Refrigerator Centrifuges

In performance, compactness and appearance these three large capacity refrigerator centrifuges set new standards.

The "Mistral 6L" has exceptionally large capacity and is a "de luxe" model incorporating such refinements as electronic speed control and preselection, stainless steel working top lid, as well as extremely high performance over a wide range of heads.

The "Mistral 4L" has rather less total capacity but is designed for the same applications, namely temperature controlled centrifuging in all types of biological laboratories, in blood processing laboratories, and in the pharmaceutical industry. A wide choice of heads and accessories accommodates large bottles and a range of all important tubes down to micro sizes.

The "Mistral 2L" is designed for low temperature centrifuging where a maximum bottle size of 380 ml is adequate. It is extremely compact and space saving.

A Superspeed Unit for the high speed centrifuging of smaller volumes is available for all three models.

	"MISTRAL 6L"	**"MISTRAL 4L"**	**"MISTRAL 2L"**
Maximum bottle size	1,250 ml.	1,000 ml.	380 ml.
Maximum total capacity	6 litres	4 litres	1,520 ml.

AND 74 COMPOUNDS

These compounds are being made available world-wide for the first time, following the discovery by Imperial Smelting Corporation Ltd. and at the University of Birmingham, of a new and attractive synthetic route. They open up exciting possibilities in such fields as polymers, pharmaceuticals, dyestuffs and agricultural chemicals, where the presence of a fluorinated aromatic ring may lead to novel properties. Many companies and university research departments are taking experimental quantities of these fluorocarbon compounds and carrying out their own programmes of investigation.

	C	Normal saline Daily* for 2 weeks	10	4·9 ± 3·45	10·3 ± 0·43	5·95 ± 0·16

* Except Sunday.

Male Sherman rats, 4 weeks old, were caged individually in an air-conditioned room (72° F), lighted artificially from 5 a.m. until 8 p.m. Ground 'Wayne Lab Blox' and water were available at all times. These young rats were injected with serum from adult rats of the same strain, prepared from blood withdrawn by direct heart puncture under light ether anæsthesia. Serum was separated by refrigeration for 1 h followed by centrifugation and was refrigerated until injected 3 h later. Treated rats received 1·5 ml. of pooled serum per 100 g body-weight by intraperitoneal injection. Rats of Exp. 1 (Table 1) received a single injection of serum and were killed 16 h later; rats of Exp. 2 were injected daily, except Sunday, at 5 p.m. (E.S.T.), for 2 weeks (13 injections). Fresh serum was prepared each day for rats of Exp. 2. Untreated rats, receiving no injections, served as controls for both experiments. A group of rats injected with saline served as additional controls in Exp. 2.

Rats were killed by chloroform inhalation between 8.30 and 11 a.m. (E.S.T.) following the last injections. Slices of liver from the median lobe were used for mitotic counts. In Exp. 1, the livers were fixed in Carnoy's fluid, and 10-μ paraffin sections stained with gallocyanin were used for counts. In Exp. 2, the livers were fixed in Bouin's fluid and the method of Ross and Flaharty[4] was used to stain the slides.

Counts of mitotic cells and the number of cells per field were made under oil immersion (× 1,250). All phases of mitosis were counted. Doubtful prophases and telophases were recorded; two doubtfuls were taken to equal one mitosis. Mitotic rates, expressed as the number of mitoses per 1,000 cells, were calculated from the number of mitoses in 100 fields and an estimate of the number of cells in 100 fields. Approximately 9,000 cells were examined in each rat's liver.

As shown in Table 1, the mean mitotic rate of the rats which received a single injection of serum was the same as that of the controls. In Exp. 2, the mitotic rate of the serum-treated rats was less than the other two groups, but the difference was not statistically significant. It might be said that insufficient rats were used, and that, if more rats had been used, it would have been possible to demonstrate statistically significant differences. The number of rats needed to demonstrate the statistical significance of specified differences can be calculated by Sillitto's method[5] using the standard deviation of the untreated controls. To demonstrate differences ($P = 0{\cdot}05$) amounting to 10, 25 and 50 per cent of the control mean, 106, 30 and 8 animals per group, respectively, would be needed. Thus, in the present experiment, sufficient rats were used to demonstrate a reduction of mitotic rate of about 50 per cent. Liver weights were also unaffected by repeated injections of serum from adult rats. The mean wet weights and relative weights of the livers of all three groups of Exp. 2 were nearly the same.

Thus inhibition of mitotic activity in livers of young, rapidly growing rats was not evident after a single injection of serum from adult rats or after prolonged treatment with serum. Similarly, Stich[6] found that injections of liver homogenate inhibited mitotic activity in regenerating livers but had no effect on growing livers of baby rats. The lack of effect in livers of young rats of treatment which inhibits mitosis in regenerating liver would seem to be important in view of Bullough's[7] recently proposed theory of mitotic control in adult mammalian tissue. Starting with the premise that any cell naturally prepares for mitosis unless diverted to differentiate, Bullough suggested that control of mitotic activity within a given tissue is accomplished by a tissue-specific mitotic inhibitor (chalone) which prevents further preparation for mitosis and promotes differentiation. It follows that this mechanism would not be operative in controlling mitotic activity in tissues of young, rapidly growing animals. Thus livers of young rats may fail to respond to treatments which inhibit mitosis in regenerating livers because differentiation cannot be promoted.

Leptospira erinacei auriti in a Water Vole, *Arvicola amphibius*

DURING the course of an investigation made by the Central Veterinary Laboratory into the incidence of leptospiral infection in small wild mammals a number of strains were recovered. Most of these apparently belong to the *hebdomadis* group, but one strain, *W.V.*14, from a water vole, was serologically in the *autumnalis* group. It was finally identified in Amsterdam as *L. erinacei auriti* as shown in Table 1. An apparent relationship to grippotyphosa and butembo in cross-agglutination tests was not confirmed by absorption tests.

Occurrence of *Asellus* (Crustacea. Isopoda) in Esthwaite and Ullswater, English Lake District

IN a previous paper[1] *Asellus aquaticus* was recorded for Esthwaite from one station only, and it was also stated that *Asellus* was absent from Ullswater. Since then the situation has changed, as *Asellus aquaticus* is now established throughout Esthwaite and *Asellus meridianus* has been found at the south end of Ullswater.

The implications of this are of sufficient interest to warrant full publication, but the following points may be made now. In the case of Esthwaite, it seems from old records that *Asellus* was definitely recorded from the boat house and reed bed area at the north end in 1950, although it is possible that it may have been seen as early as 1944. Despite my own collections in Esthwaite in 1948 and 1951 and those of the Freshwater Biological Association supply department in intervening years, *Asellus* was not reported again until 1955—again around the boat house, one of the places where I collected in 1948. This raises the point as to whether it is more prudent to record a species 'as not found' rather than 'absent'. One has on several occasions, after prolonged and vigorous collections in the Midlands and in the Lake District, found a single specimen of *Asellus*. How often on other occasions must the odd specimen have been overlooked despite every care ?

Esthwaite is 1·5 miles long and less than 0·5 miles across at its widest, and after 14 years *Asellus* can be found around the whole lake and to a depth of 3–4 m. Whether this represents a genuine 'spread' of *Asellus* from a single centre, or the build-up from a population so diffuse that the collecting methods used failed to detect it, is a matter for consideration. It would be extremely interesting to re-examine the other lakes in the district where I previously failed to find *Asellus*. So far as the Ullswater district is concerned the only other known occurrence of *Asellus*, after many years collecting, is in three garden pools above the lake. One of these pools contains *A. aquaticus*, the other two *A. meridianus*, and *Asellus* is known to have been introduced with weeds. The pools are a mile away in direct line from the *Asellus* localities in Ullswater, and apart from these the nearest known occurrence is in Windermere, ten miles away over Kirkstone Pass.

I thank Mr. S. Nield and Mr. J. D. Allonby, of the supply department of the Freshwater Biological Association, for their help with the Esthwaite records and for the first record of *Asellus* in Ullswater.

Antifungal Activity in Orange Tissue infected with *Aspergillus niger*

ORANGE fruits that had been wounded and inoculated at fixed points with conidia of *Aspergillus niger* became infected with *Penicillium digitatum*, and it was observed that growth and sporulation of the latter were halted some distance from the regions of the fruit colonized by *A. niger*. Cylindrical portions of the pulp from regions supporting the *A. niger* growth placed on plates of potato–dextrose agar seeded with the spores of various fungi inhibited the growth of several, but no such inhibition was obtained with pulp from healthy fruits (Table 1).

Furthermore, macerated orange pulp when inoculated with *A. niger* developed similar antifungal activity although potato–dextrose agar, which was supporting *A. niger*, did not. Therefore, in further investigations, peeled oranges were macerated in a Waring blender and the homogenate was distributed in 11-cm diameter Petri dishes in layers approximately 0·7 cm deep. After inoculating the surface of the fruit pulp at several points with a suspension of *A. niger* conidia in water, the dishes were incubated at 25° C for four days, by which time the surface was covered with a thick mycelial mat on which conidial heads were just developing. This was lifted, the adhering pulp brushed from its underside into the residual liquid and the mat discarded. Sufficient alcohol was added to bring the final concentration in the treated pulp to 80 per cent ethanol and the mixture was left at 4° C for 24 h to precipitate proteins. It was then filtered and the residue, which had no antifungal activity, was discarded. The alcohol was removed from the filtrate at 30° C under reduced pressure when lipid material separated. This was filtered off; it was non-fungitoxic and was discarded. The remaining clear aqueous solution was highly acidic, strongly antifungal to *A. brassicicola*, less so to *B. cinerea* and inactive against *A. niger*.

Table 1. DIAMETER OF ZONE OF INHIBITION (MM) CAUSED BY HEALTHY OR *A. niger*-INFECTED FRUIT (5 MM^3 PORTIONS)

Test organism	Healthy	Infected
Alternaria brassicicola	0	43
Aspergillus niger	0	0
Botrytis cinerea	0	0
Cladosporium cucumerinum	0	26
Glomerella cingulata	0	0
Penicillium digitatum	0	31

Laboratory investigations indicated that spores of *A. brassicicola* were acid-sensitive, and when samples of deproteinized aqueous extracts of both healthy and *A. niger*-inoculated pulp were passed through columns of ion-exchange resin ('Amberlite *IR*-4*B*(OH)') to remove acidic constituents fungitoxicity was lost. The adsorbed acids were eluted from the columns with 6 N formic acid which was then removed under reduced pressure. Two-dimensional chromatography of the eluted acids showed that citric acid was the predominant acid in both extracts. Titration against standard alkali indicated an equivalent of approximately 4,000 μg/ml. of citric acid in healthy pulp and 28,000 μg/ml. in infected pulp. The degree and range of antifungal activity exerted by citric acid solution at the above concentrations correlate closely with that of the supernatant from centrifuged healthy and *A. niger*-infected pulp (Table 2).

Table 2. DIAMETER OF ZONE OF INHIBITION (MM)* CAUSED BY 0·1 ML. OF JUICE OF HEALTHY OR INFECTED ORANGE AND OF TWO LEVELS OF CITRIC ACID SOLUTION

Test organism	Healthy	Infected	Citric acid (28 mg/ml.)	Citric acid (4 mg/ml.)
Alternaria brassicicola	0	41	45	15
Aspergillus niger	0	0	0	0
Botrytis cinerea	0	20†	20†	0
Penicillium italicum	0	0	0	0
Penicillium digitatum	0	27	26	0

* Diameter of filter paper disk, 13 mm. † Retarded growth.

Thus it would seem that much of the antifungal activity shown by *A. niger*-metabolized orange tissue towards certain fungi is due to citric acid production, though further experiments have indicated that other antifungal materials are present. The —OH resin-treated aqueous extract from infected pulp was of low activity, but an ethyl acetate extract was toxic to the spores of *A. brassicicola* at 250 μg/ml., though less active against *Glomerella cingulata* and *Botrytis cinerea* and inactive against *A. niger*. Similar extracts from healthy pulp were inactive below 5,000 μg/ml. against all the test fungi. Furthermore, some other fungi, for example, *Glomerella cingulata*, when inoculated into orange pulp, produce ethyl acetate-soluble antifungal materials without the large production of citric acid characteristic of *A. niger*.

The development of antifungal activity in plant tissues as a result of infection by pathogens has recently received considerable attention[1]. The resistance to further infection by orange tissue already infected with *A. niger* can therefore be considered in relation to the production of phytoalexins[2], substances defined as "antibiotics which are produced as a result of the interaction of two metabolic systems, host and parasite, and which inhibit the growth of micro-organisms pathogenic to plants"[3]. In this sense, citric acid, although present in healthy fruit at a non-toxic concentration, might be regarded as a phytoalexin since it reaches toxic levels through the activity of the invading pathogen. The ethyl acetate soluble antibiotic remaining after the removal of acids could likewise be considered as a phytoalexin.

Thermal and Translocated Induction of Endophytic Mycelium in two Powdery Mildews

Endophytic mycelium of various biotypes of *Erysiphe graminis* was demonstrated by Salmon[1] in cereal leaves which had been mechanically damaged or heated to 50° C for short periods immediately prior to inoculation. Schnathorst[2] obtained endophytic mycelium of *E. cichoracearum* in lettuce leaves by stripping one epidermis and inoculating the exposed mesophyll. Yarwood[3] found that heat both predisposed cucumber cotyledons to infection by *Sphaerotheca fuliginea*[4] and made them less responsive to subsequent heat therapy. Yarwood[5] also demonstrated that heat treatment, abrasion or infection by *Uroymces phaseoli* rendered *Phaseolus vulgaris* susceptible to infection by *S. fuliginea*, by which it is not normally attacked, and Yarwood *et al.*[6] and Nienhaus and Yarwood[7] showed that some effects of heating one leaf of an opposite pair could be transmitted to the other, for example, increased susceptibility of bean and cowpea to a strain of tobacco mosaic virus.

Continuing this type of work with *S. fuliginea*, it was observed that when one of a pair of cucumber cotyledons, about 14 days old, was heated in water at 45°, 50° or 55° C for periods of $\frac{1}{2}$–120 sec, either 12 h before inoculation of the upper surface of both cotyledons, or up to 7 days after inoculation, the mycelium became endophytic in both cotyledons. Similar results were obtained in experiments made with the first true leaves of sunflower seedlings inoculated with *E. cichoracearum*.

Thermal induction of endophytic mycelium, first noted by Salmon[1], was confirmed in barley seedlings inoculated with the barley isolate of *E. graminis*, although here no translocated effect was observed.

In all cases, an intercellular mycelium was formed, and typical haustoria were formed in the mesophyll and palisade cells, in the parenchyma of the vascular bundles and in the opposite uninoculated epidermis. Conidiophores and conidia were formed externally on this and on the inoculated epidermis and also occasionally in the intercellular spaces, variously orientated to the leaf surface.

In sunflower and cucumber the effect in the heated leaf varied with the duration and temperature of the treatment and that in the opposite unheated leaf varied similarly, though to a lesser extent. As the duration of the heat treatment was extended a bimodal response became apparent in the curve relating effect to duration, and the development of endophytic mycelium was further affected by the time of day at which the treatment was made, by the time of year and by the age of the plant. Thus, in August, 11-day-old cucumber seedlings showed the greatest effect when one cotyledon was heated at 0700 h following inoculation at 1700 h the previous day, while in 14-day-old plants this occurred following heating at 1300 h, and the effect diminished progressively for the succeeding 5 months.

Salmon[1] found that cross-infection with isolates of *E. graminis* from various cereals and grasses became possible after heat treatment of the hosts; similarly, in the work recorded here, cross-infections with *E. cichoracearum* and *S. fuliginea* were observed. While, however, both isolates produced an endophytic mycelium in sunflower, *E. cichoracearum* from sunflower failed to become endophytic in cucumber. As Yarwood[5] demonstrated, *S. fuliginea* from cucumber infected leaves of *Phaseolus vulgaris* containing heat-killed mycelium of *Uromyces phaseoli*; further heat treatment of one of a pair of such leaves induced the mycelium of *S. fuliginea* to become endophytic, but in the rusted tissues only. This effect was again translocated to the unheated leaf.

When crude sap extracts were made from cucumber cotyledons at intervals after heat treatment, and applied to one cotyledon of other plants, which were then inoculated with *S. fuliginea*, an endophytic mycelium was formed, both in the treated and the untreated cotyledons. It is suggested that an active principle predisposing the cucumber cotyledons to this type of infection is formed as a result of the heat treatment and translocated; in bean two substances formed in response to heat and translocated have been demonstrated and to some extent characterized by English *et al.*[8,9].

This work was supported by a grant (*G*9820) from the U.S. National Science Foundation, and carried out in the laboratory of Dr. C. E. Yarwood, whose advice is gratefully acknowledged.

MICROBIOLOGY

Release of Cores from Bacterial Spores by Mechanical Breakage in Acidic Media

The dormant bacterial spore consists of a core surrounded by a structure called the cortex which in turn is bounded by a structure called the coat. The core contains cytoplasm plus nuclear material and the cortex contains mucopeptide[1]. The coat is mainly protein[2,3] with a high cystine disulphide bond content[4]. We have been unable to liberate cores by enzymatic digestion of spore coats using a variety of proteolytic enzymes including keratinase[5] before or after treatment of spores with reagents which rupture disulphide bonds[6]. We therefore investigated the possibility of releasing cores by mechanical breakage of spores.

Bacterial spores can be broken by shaking spore suspensions with Ballotini beads in the Mickle tissue disintegrator; but no recognizable cores are released by this process. The mechanical resistance of vegetative cells and protoplasts depends on the hydrogen ion concentration[7] and we therefore examined the effect of *p*H on the mechanical breakage of spores. The extent of breakage was followed by phase contrast microscopy. When bacterial spores (19 strains of *Bacillus* and 1 *Clostridium* strain) were shaken in the Mickle apparatus with Ballotini beads below pH 4·2, the cores became separated from the broken coats and existed as free phase bright bodies. The free cores of *Bacillus subtilis* spores were examined in detail. They were ovoidal, about 0·5μ long, and resembled small spores except that they were not so phase bright. The chemical nature of the buffer present during core production did not affect the appearance of the cores obtained, but the pH value was important, and no free cores were seen when spore breakage was performed above pH 4·2.

There was no change in the phase bright appearance and shape of cores made at pH 3 when the pH was raised to 4·2–6·5. However, at about pH 7·0 cores became swollen and phase dark; above pH 8·0 cores became still more swollen, pale and irregular in outline. These effects of pH change were instantaneous. Swollen cores at pH 6·5–9·0 shrank and became phase bright again when the pH was changed to 3·0. Spores that had just become phase dark during germination yielded phase bright cores when broken at pH 3·0 and these responded to pH in the same way as those prepared from dormant spores. Cores at pH 5·8 were not resistant to breakage even though they were in a shrunken and phase bright state.

Bacterial spores contain dipicolinic acid (DPA)[8] and calcium[9]. DPA forms 5–15 per cent of the dry weight of the spore and calcium occurs in slightly greater than equimolar amounts to the DPA[10]. The effects of DPA and calcium (25 and 50 mM) on cores were therefore tested; neither had any effect on the appearance of phase-bright cores at pH 6·0 and mixtures also had no effect (Ca : DPA ratios of 0·5, 1·0 and 2·0). Calcium ions (25 mM) in *tris* buffer pH 9·0 prevented the formation of pale swollen cores, but this protective effect was annulled when DPA (50 mM or 25 mM) or 'Versene' (1 per cent w/v) was also present. Excess calcium (50 mM) over DPA (25 mM) prevented the formation of pale swollen cores. Cores remained shrunken and phase bright in pH 8·2 *tris* buffer when 25–100 mM calcium was present. The protective effect of calcium ions was also shown by other divalent cations (25 mM), that is, barium, strontium and magnesium, by the trivalent cation lanthanum (25 mM), and by spermine (1 per cent w/v). The following monovalent cations (25 mM) were not protective: sodium, potassium, lithium, ammonium and cæsium. Inorganic or organic anions (Cl^-, NO_3^-, SO_4^{2-}, citrate, acetate, phosphate, veronal) had no observable effect on cores.

We suspected that the cores would be surrounded by some cortical mucopeptide, and we examined the effects on cores of agents known to complex with mucopeptide, that is, alcian blue (1 per cent w/v)[11] and auto-inhibitory concentrations of lysozyme (1–1·6 per cent w/v)[12]. Both reagents prevented phase darkening of cores as the pH was raised above 7·0. Complexing of lysozyme with cores was confirmed visually by using fluorochrome-labelled lysozyme which specifically stains mucopeptide[13]. Similarly, alcian blue stained cores but not coats. These staining reactions suggested that the cores contained mucopeptide. This was confirmed by analysis of the mucopeptide constituent hexosamine in core + coat fractions of *Bacillus subtilis* and *B. cereus* spores[14]. Depending on the species, 30–50 per cent of the spore hexosamine was rendered soluble during core formation at pH 3·3 and a further 20 per cent during phase darkening of cores at pH 6·6; the phase dark core + coat fraction at pH 6·6 retained 25–50 per cent of the spore hexosamine.

Core + coat fractions of *B. subtilis* and *B. cereus* spores contained less than 5 per cent of the spore DPA, estimated colorimetrically[15] and spectrophotometrically[16]. Thus most of the spore DPA was lost during the preparation of the coat + core fraction. This suggested that DPA may be located in the cortex of the spore.

Bacillus subtilis cores formed in the pH range 3·3–4·1 did not give rise to colonies when incubated on yeast glucose agar, nor did they grow when incubated in slide cultures and examined periodically under the microscope.

The effect of hydrogen ions on cores can be explained i terms of their effect on the relative numbers of positive and negative changes of the core macromolecules. I the pH region 2·0–4·2 the core is near its isoelectric point and so can exist in a contracted state which probabl accounts for the mechanical resistance of the core below pH 4·2. Above pH 4·2 and up to about pH 6·5 the core is still in a contracted state but is more susceptible t mechanical damage. Above pH 6·5 insufficient hydrogen ions are present to neutralize negative charges in the core so swelling occurs. Di- and tri-valent cations and spermin probably prevent swelling of cores by cross-linking pair of carboxyl groups. Monovalent cations are ineffective because they cannot form cross-links. Lysozyme and alcian blue may also prevent swelling of cores by a cross linking reaction that is specific for mucopeptide.

We think it likely that the cores of dormant spores are in a contracted state like cores below about pH 6·5 o like calcium-protected cores above pH 6·5. The possibility that the core of the spore is in a contracted state could help to explain the phenomenon of spore heat-resistance as suggested by von Daryáni[17]. How the core could get into such a state during sporulation is not known, but perhap it is by a mechanism similar to the contractile cortex suggested by Lewis, Snell and Burr[18]. Warth *et al.*[1 suggested that the mucopeptide cortex could behave like a weak cation exchange resin and that the spore calcium could cause the cortex to contract during sporulation. DPA is difficult to account for in this theory, because it chelates calcium and annuls the effect of calcium on cores. Thus DPA could annul any contracting effect of calcium during sporulation. However, the rigid spore coat may also be involved in maintaining contraction and the DPA may be located in a different region of the spore from the calcium. Investigations such as those of Alderton *et al.*[20], who demonstrated cation exchange reactions with spores and related them to heat resistance seem very pertinent to the elucidation of the roles of calcium and DPA in the structure and heat resistance of spores.

Enumerating Viable Bacteria

For many purposes the number of viable organisms has to be known. In antibiotic assays, for example, the size of the inoculum influences the result of the test[1,2]. Optical densities of bacterial suspensions, not corroborated by viable counts, are misleading, as dead cells are also registered. Viable numbers are usually estimated from poured plates[3].

As plating has its limitations, an attempt was made to compare optical densities with viable counts, obtained by two other methods. The first method is based on the presence and absence of organisms in broth samples. The mean number of organisms in the broth tubes can be calculated from the Poisson series[4]. 155 test-tubes are needed, at the point of maximum accuracy, in order to obtain a standard error of sampling of 10 per cent. If the mean number of organisms per sample exceeds 2, this method becomes inaccurate. The second method is based on filtration through membrane filters, which retain bacteria. The membrane filters, after filtration, are laid on top of a broth-soaked pad, incubated for 24 h, and the colonies counted. This method, in contrast to the poured plate method, permits the enumeration of viable bacteria, even if only a few organisms are present in large volumes of fluid. Consequently, the same dilution can be used in both methods. For example, a mean of one organism per sample results in 36·79 per cent sterile tubes and in 63·21 per cent fertile tubes[5]. Filtering 100 ml. of this same dilution through a membrane filter should yield 100 colonies.

In experiments with 17–18-h-old cultures of *Staphylococcus aureus*, type 81, the mean bacterial numbers, obtained by both methods, differed, on the average, by 9·22 per cent. These results are based on 1,124 tubes and 31 filtrations.

The optical density of 17–18-h-old broth culture was determined at 640 millimicrons in a 1 cm cuvette. The concentration of this bacterial suspension was assumed to be unity. Dilutions were prepared, and their optical densities found. Sterile broth served as blank.

Optical densities were plotted versus relative bacterial concentrations. It was found that to points, ranging from about 0·3 to 0·7 optical density, a straight line could easily be fitted. It also turned out that readings obtained in this range are more accurate than readings obtained outside this range, because between 0·3 and 0·7 a smaller change in bacterial concentration corresponds to one scale part on the percentage transmission scale.

In this range a high and significant coefficient of correlation (0·9987) between relative bacterial concentrations and optical densities was found. The regression line was found to be:

$$x = 1{\cdot}0136\,y - 0{\cdot}09216 \qquad (1)$$

where x stands for relative bacterial concentration, and y for optical density.

Simultaneous determinations of optical densities and viable counts, by both methods, rendered it possible to assign absolute viable numbers to relative bacterial concentrations. Substituting for x the absolute viable count per millilitre, the right side has to be multiplied by a factor, f, in order to maintain the validity of equation (1):

$$\text{Viable number} = (1{\cdot}0136\,y - 0{\cdot}09216)\,f$$

whence

$$f = \frac{\text{Viable number}}{1{\cdot}0136\,y - 0{\cdot}09216} \qquad (2)$$

A mean value for f was determined by carrying out 31 comparisons of optical densities and filtrations, and found to be: $9{\cdot}05947 \times 10^{8}$.

Solving the equation for y, optical densities are obtained, which correspond to viable numbers:

$$y = \frac{\text{Viable number} + 0{\cdot}09216\,f}{1{\cdot}0136\,f}$$

or substituting for f its value:

$$y = \frac{\text{Viable number}}{9{\cdot}18268 \times 10^{8}} + 0{\cdot}09092 \qquad (3)$$

For a viable number of 1×10^{8}/ml., for example, the optical density, calculated from equation (3), becomes 0·19982, which is slightly outside the sensitive range. A 17–18-h-old broth culture was diluted to this optical density. From a 10^{-8} dilution of this strength two samples of 100 ml. each were withdrawn and filtered. One sample yielded 92 colonies, the other 98, instead of the 100 colonies expected.

Transmission of Colicinogeny to *Providence* Strains

COLICINOGENY has been transmitted to non-colicinogenic strains of *Escherichia coli* and *Shigella*[1], *Klebsiella*, paracolons, *Salmonella*[2] and *Serratia*[3]. Hamon[2] tried unsuccessfully to pass this property to *Proteus* cultures. *Providence* strains (unpublished observations) are not bacteriocinogenic for genera of the family Enterobacteriaceae and are not susceptible to the various colicines.

The *Providence* strains used were N.C.T.C. Nos. 9204, 9248, 9250, 9260, 9268, 9294, 9295, 9278, 9283 and 9298. Standard colicinogenic strains and appropriate colicine-indicator cultures were kindly supplied by Prof. P. Fredericq and covered the range from *A* to *K* and *V*. Mutants resistant to 1 mg/ml. streptomycin of the *Providence* and colicine-indicator strains were selected and the transfer of colicinogeny from Fredericq's streptomycin-sensitive strains to the resistant *Providence* cultures was attempted according to the methods of Fredericq[1] and Ozeki *et al.*[4]. *E. coli* strain *CA*.23 transmitted colicine factor *D* to *Providence* strains N.C.T.C. 9260, 9278, 9283, 9295, 9298 and paracolon strain *CA*. 62 transmitted colicine factor *J* to strain 9295. Strain *CA*. 62 produces colicines *J* and *I*, but colicine factor *I* was not detected in 213 colicinogenic colonies of strain N.C.T.C. 9295 tested. No other colicine factors were transmitted to any of the strains and thus exactly half the strains accepted colicinogeny. Direct cell contact appeared essential for transmission of colicinogeny since the use of cell-free culture filtrates of donors was unsuccessful. The fraction of cells of the acceptor population which acquired colicinogeny was never more than 10^{-3} and usually the selection process had to be repeated on the growth picked off to obtain well-separated colicinogenic colonies. Control experiments with only the acceptor *Providence* strains never produced inhibition of the indicators. Ozeki *et al.*[4] reported a fraction of 10^{-4} for *S. typhimurium* cells accepting colicine factor *K* from *E. coli K*49.

The colicinogenic *Providence* strains have the same biochemical reactions and phage-susceptibility patterns[5] as corresponding non-colicinogenic cultures, and the colicines produced by the *Providence* cultures appear to be identical with those produced by the original strains. After storage for 9 months on agar slopes at room temperature the colicinogenic *Providence* cultures were streaked out for single colonies and tested for colicine production. All colonies were still colicinogenic. The colicinogenic property of the cultures is also not affected by exposure to acriflavine[6]. Attempts at intrastrain passage[7] of colicine factors *D* and *J* have been unsuccessful so far. In *Salmonella*[4] only factors *B*, *E*1 and *I* are capable of independent intrastrain transfer and these factors also promote the passage of other colicine factors present. In *Serratia* factor *I* behaves similarly[3]. None of these factors has yet been introduced into *Providence* strains and this may account for the failure of intrastrain transmission.

This work was aided by grants from the South African Council for Scientific and Industrial Research.

A Factor required for Growth Initiation of *Pasteurella tularensis*

Previous investigations[1,2] established the essential requirements of *Pasteurella tularensis* (*P. tularensis*) for growth in both complex and chemically defined media. However, the media described sustained luxurious growth of *P. tularensis* when relatively large numbers of cells (about 10^6 to 5×10^6/ml. medium) were used for inoculation. Attempts to reduce the size of the inoculum by supplementing the media with a variety of vitamins, tissue extracts and other preparations noted for their growth-promoting ability, were by and large unsuccessful. The nutritional fastidiousness of *P. tularensis* appeared particularly puzzling in view of the notoriously extreme infectivity of this micro-organism, which is reputed to be capable of multiplying *in vivo* out of a few cells[3]. Furthermore, both highly virulent and completely avirulent strains exhibited the same pattern of growth requirements.

A clue for at least a partial resolution of this paradox was provided by an observation incidental on another line of investigation concerned with the exceptional susceptibility of low tonicity exhibited by *P. tularensis*. It was noted that a brief exposure of *P. tularensis* cells to a hypotonic environment resulted in a disruption of their permeability barrier, as evidenced by the leakage of intracellular constituents and the concomitant drastic decline of viability[4]. The viability of the so injured cells was found to be largely restored in the presence of a concentrate prepared from the suspending medium containing the material which leaked out of the osmotically shocked cell suspension ('leakage material'). Moreover, culture media fortified with the leakage material acquired the ability to support growth of the intact organism from apparently single-cell inocula, thus permitting the performance of viable counts which were otherwise not feasible with the strains tested by us.

The substance responsible for the growth initiating effect was found to be elaborated by the proliferating *P. tularensis* cells and to diffuse out in the course of growth into the surrounding medium. The active factor proved to be of low molecular weight, and owing to its relative stability and resistance to various chemical and physical treatments could be readily concentrated and extensively purified[5]. Work designed to procure sufficient quantities of the purified material for chemical analysis and biochemical studies is now in progress.

CYTOLOGY

A Yeast Mitogenic Factor Active on Human Peripheral Leucocytes in Culture

We have observed that the addition of zymosan-treated sera to short-term human peripheral leucocyte cultures leads to a slight but significant increase in mitotic frequency. Inactivation of serum complement by zymosan[1] as an important factor in the increase in mitotic frequency was ruled out, and it could be shown that an active mitogenic factor was extracted from zymosan during treatment of the sera. It was found that a more active mitogenic factor could be extracted directly from whole frozen yeast (*Saccharomyces cerevisiae*) and this extract was then used exclusively. The method of extraction consisted of overnight incubation at 37° of equal volumes of saline washed cells and 0·2 N potassium hydroxide, followed by centrifugation at 2,000 r.p.m. for 30 min. The resulting supernatant was neutralized with perchloric acid, and then passed through a 'Sephadex' DEAE column which had been washed with 0·2 M *tris* buffer at *p*H 7·1. Before use, the yeast extract (*YAF*) was sterilized in boiling water for 30 min. Leucocyte suspensions were obtained by dextran sedimentation (2·5 ml. 6 per cent dextran per 10 ml. heparinized blood at 37°). Colchicine (0·02 μg/ml. culture) was added 8–10 h before collecting and chromosome preparations were made according to the method of Hungerford *et al.*[2].

The mitogenic factor in the crude 0·2 N potassium hydroxide extract is non-dialysable, acid labile (1 N hydrochloric acid for 20 h at room temperature), heat resistant, and is not retained by either an anion or a cation exchange column. The crude extract contains protein[3], phosphorus[4], and hexose[5] in approximately equimolecular amounts. It is resistant to digestion by ribonuclease, sensitive to digestion by alkaline phosphatase and lysozyme, and partially sensitive to trypsin.

The frequency of mitoses observed in more than 40 experiments varied from 0·4 to 3·0 per cent; the mitotic index always being significantly higher than that observed in control cultures, and lower than in cultures treated with phytohæmagglutinin (PHA). The peak of mitotic activity occurred between the fifth and sixth day of culture, although it was possible to observe occasional metaphases in cultures incubated for 20 days. Titration experiments with the same preparation of yeast extract always showed a limited region of linear mitotic response to increasing *YAF* concentration, followed at higher *YAF* levels by inhibition of mitoses and occasionally toxicity. It is possible that some of the responses of cultures to higher *YAF* levels might be due to impurities in the crude extract. This question can only be resolved when a purer preparation of the active factor is available.

An additive mitogenic effect was obtained when PHA and *YAF* were added to the same culture. This suggested that *YAF* was acting on a cell population different from that which was sensitive to PHA. To characterize this difference further, a comparative examination of DNA replication was undertaken in *YAF*, PHA, and *YAF* plus PHA treated cultures. Tritiated thymidine (Schwarz 1·5 c./mM, 0·2 μc./ml.) was added at the beginning of the cultures and left until collected, at which time slides were prepared for autoradiography (Kodak *NTB* 3 emulsion). After exposure for one week, the slides were developed, stained, and then scored for labelled and unlabelled metaphases.

Table 1. Percentage of Metaphases with Varying Grain Counts in Different Cultures

Cultures	No. of grains per metaphase 0	 1–10	 10–20	 20–30	 30–over	Total metaphases counted
PHA*	0	25	12	22	41	59
YAF†	67	23	7	2	1	105
YAF+PHA	6	15	25	21	33	33

* PHA, phytohæmagglutinin. † *YAF*, yeast extract.

The results of this work, given in Table 1, show that all the metaphases in the PHA culture were labelled, while most of the metaphases in the *YAF* culture were unlabelled. In the *YAF* plus PHA culture nearly all the metaphases were labelled (94 per cent).

The 100 per cent labelling of metaphases in the PHA culture confirms a previous report[6] and indicates that PHA sensitive cells are in the pre-DNA synthetic period (*G*1) prior to culture. The fact that most of the metaphases were unlabelled in the *YAF* culture suggests that most of the *YAF* sensitive cells are in a post-DNA synthetic period (*G*2) prior to culture. Since most of the metaphases in the *YAF* plus PHA culture were labelled and many heavily so, it would seem that inhibition of uptake and incorporation of thymidine by *YAF* is not responsible for the many unlabelled metaphases in the *YAF* culture.

Rather our results seem to indicate that the majority of the cells stimulated by *YAF* to divide have already undergone DNA replication before the initiation of the cultures, and that a small portion (lightly labelled) are apparently terminating DNA replication when the culture is started. Several authors have reported the existence of a small fraction of nucleated blood cells which undergo DNA replication while in circulation[7,8]. However, under physiological conditions, no mitotic figures are observed in peripheral blood smears. Although the frequency of the cells in active DNA synthesis varies considerably in the different reports (0·06–0·5 per cent), it is generally higher than the frequency of mitotic figures observed in cultures initiated without the addition of any agent.

It appears, then, that the circulating leucocytes consist of at least three populations with respect to their ability to complete cell division *in vitro*: (1) a major population of cells that are in their *G*1 phase and are stimulated to divide by PHA; (2) a minor population of cells that are in *G*2 and are stimulated to divide by *YAF*; and (3) a very small population of cells which are able to divide spontaneously.

This work was supported in part by research grant *G*–14825 from the U.S. National Science Foundation.

SOIL SCIENCE

Influence of Nitrogen on the Availability of Fertilizer Phosphorus

THE beneficial effects of additions of nitrogen on the availability of fertilizer phosphorus have been investigated with various techniques, such as when nitrogen is mixed with the soil and phosphate added as placement, when both nitrogen and phosphate are added separately or when nitrogen and phosphate are added in intimate association. With the view of investigating the influence of nitrogen on the availability of fertilizer phosphorus, under conditions of both nutrient sources being mixed with the soil, work described here was carried out on two soils (important characteristics given in Table 1) using wheat as a test-crop through greenhouse pot-culture experiments, involving the use of radiotracer techniques.

Table 1. MAIN CHARACTERISTICS OF SOILS

No.	Soil	*p*H (1 : 2·5 ratio)	% organic N (Kjeldahl's method)	Available P_2O_5 (lb./acre Olsen's method)*	% free $CaCO_3$ (Collins calcimeter)	Cation exchange capacity (m.equiv./100 g)
I	Alluvial soil I.A.R.I., N. Delhi	7·8	0·07	37·0	0·69	10·21
II	Alluvial soil Sabour (Bihar)	6·2	0·08	10·0	Traces	5·22

* *U.S. Dept. Agric. Circ.* No. 939.

Table 2. INFLUENCE OF UREA ON THE AVAILABILITY OF PHOSPHORUS FROM SUPERPHOSPHATE

	Soil I				Soil II			
Treatment	Total P (mg/pot)	% uptake	Fert. P (mg/pot)	% utilization	Total P (mg/pot)	% uptake	Fert. P (mg/pot)	% utilization
Control	3·30	—	—	—	1·88	—	—	—
P	3·56	49·43	1·74	8·89	3·78	56·65	2·15	10·87
N_1+P	5·21	48·02	2·74	13·82	3·91	62·27	2·35	11·89
N_2+P	5·32	63·05	3·48	17·06	4·32	64·68	2·40	12·12
S.E.M.*	0·30	2·22	0·24	1·19	0·23	1·87	—	—
L.S.D.† at 5% level	0·87	6·84	0·73	3·65	0·68	5·76	N.S.	N.S.

P, 40 lb. P_2O_5/acre as super: N_1 and N_2, 40 and 80 lb. N/acre as urea respectively.

* S.E.M., standard error of mean.

† L.S.D., least significant difference.

Three levels of nitrogen (0, 40 and 80 lb. N/acre) as urea were combined with two levels of phosphate (0, 40 lb. P_2O_5/acre) as superphosphate in a randomized design, and each treatment was replicated thrice. Superphosphate was tagged with phosphorus-32. The nutrient sources were mixed with the soil in an electrically operated twin-shell dry blender.

Dried composite samples consisting of three plants from each replicate were wet-ashed and analysed for phosphorus[1]. Radioactive phosphorus was determined by the method of Meckenzie and Dean[2].

In soil No. 1, the supplementary application of nitrogen as urea significantly increased the absorption of total phosphorus by wheat plants when compared with that due to phosphate application alone. Here the application of nitrogen significantly enhanced the amount of phosphorus in plants derived from the fertilizer source. In this soil, percentage utilization of applied phosphorus has also been found stimulated due to the presence of nitrogen along with the source of phosphorus. Table 2 shows that higher doses of urea significantly increased percentage uptake of fertilizer phosphorus in both the soils under examination.

Olson and Dreier[3] have shown the importance of association between nitrogen and phosphate sources in causing increased uptake of fertilizer phosphorus when applied in intimate association. Rennie and Soper[4] also found increased utilization of fertilizer phosphorus only when nitrogen was intimately associated with phosphate fertilizer.

It must be realized in the investigation recorded here that both nitrogen and phosphorus were homogeneously mixed with the soil and under these conditions the effect of nitrogen on the utilization and uptake of fertilizer phosphorus is revealed. In such cases, as here, the association between nitrogen and phosphate had definitely been maintained though to a lesser degree as compared with that in a band. Probably this association between nitrogen and phosphorus may be partly responsible for increasing the availability of fertilizer phosphorus to plants in such systems also.

I thank Dr. N. P. Datta, head of the Division of Chemistry, I.A.R.I., New Delhi, and Prof. J. Låg, director of the Institute of Soil Science, Norway, for their advice.

MISCELLANEOUS

Sintering-Cobalt – Chrome – Molybdenum Alloys for Osteosynthesis

Of the materials which have been used for surgical prosthetics, the stellite alloys (based roughly on 65 cobalt, 30 chromium, 5 molybdenum) have excellent strength and adequate corrosion resistance[1]. Unfortunately these alloys are available only in the form of castings which, in the absence of any special techniques, develop a very large grain-size in the material. Small surgical implants have cross-sectional areas comparable to this grain size which may result in their mechanical properties being dependent on the random crystal orientation of a single grain to an applied stress. The strength of the implant may also be limited by weakness of the grain boundaries in the material. Any small amounts of impurity will segregate to the grain boundaries of the casting; when the grain size is large, the grain boundary area becomes relatively small and so the impurities may reach a high concentration. It is thought that both the foregoing factors are responsible for the wide variation and unpredictability of mechanical tests carried out here[2-4]. Therefore, a refined grain structure of these alloys should have beneficial effects by (*a*) giving a truly polycrystalline material, preferably of higher purity, and (*b*) spreading any impurities more uniformly throughout the material by increasing the grain boundary area.

Table 1

Property	Cast stellite	Sintered alloy
Density (g/c.c.)	8·298	8·3–8·4
Ultimate tensile strength (tons/in.^{2})	46·8	55
Percentage elongation	10	2·5
Fatigue limit (tons/in.^{2})	13·5	40
Young's modulus	$16·1 \times 10^3$	13×10^3

Powder metallurgical techniques appear to offer the best method of combining a fine grain size with high purity. In our work the following procedure was adopted. A master alloy consisting of 6 : 6 : 1 cobalt–chromium–molybdenum, respectively, was made up under a controlled atmosphere from the pure metal powders; pure cobalt powder was added to make up the correct proportions for the final alloy, and the mixture ground down to give a mean powder size of 5μ. The resultant powder was then cold-pressed hydrostatically at 10 tons/in.^{2} and sintered under vacuum for 10 h. At no stage in the process was air allowed to come into contact with the powder, and the contamination of the unsintered compact was minimized by keeping it coated with Analar methyl alcohol. The tests which are proceeding on the sintered alloy have shown considerably greater consistency of results and a definite improvement on the mechanical properties of the cast alloy. Results are given in Table 1, and comparative fatigue curves for the two materials shown in Fig. 1. Comparison of the different microstructures (Figs. 2 and 3) shows the accumulation of impurities in the grain boundaries of the cast material and their more uniform distribution in the sintered alloy.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk are open to the public*)

Wednesday, August 26–Wednesday, September 2

British Association for the Advancement of Science (at Southampton)—126th Annual Meeting.

Wednesday, August 26

At 7.45 p.m.—Right Hon. Lord Brain, F.R.S.: "Science and Behaviour" (Presidential Address).

Thursday, August 27

At 10 a.m.—Sir Harry Melville, K.C.B., F.R.S.: "The Contribution of New Instruments to Progress in Chemistry" (Presidential Address, Section B).

At 10 a.m.—Dr. C. E. Lucas, C.M.G.: "Aspects of Marine Fisheries Research" (Presidential Address, Section D).

At 10 a.m.—Mr. G. B. Ryle, C.B.E.: "The Need for Forests in an Industrial Society" (Chairman's Address, Section K*).

At 10 a.m.—Dr. F. Lincoln Ralphs: "Responsibility and Education" (Presidential Address, Section L).

At 10 a.m.—Mr. Eric Rea: "The Age of Advice" (Presidential Address' Section M).

At 10.15 a.m.—Mr. H. G. Conway: "Engineers at the Crossroads" (Presidential Address, Section G).

At 10.15 a.m.—Prof. F. G. Young, F.R.S.: "The Biochemistry of the Endocrine System" (Presidential Address, Section I).

At 11.30 a.m.—Prof. B. R. Williams: "Economics in Unwonted Places" (Presidential Address, Section F).

At 2.30 p.m.—Prof. R. V. Jones: "Chance Favours the Trained Observer" (York Lecture).

Friday, August 28

At 10 a.m.—Mr. J. A. Ratcliffe, C.B.E., F.R.S.: "The Sun and the Ionosphere" (Presidential Address, Section A).

At 10 a.m.—Mr. A. A. L. Caesar: "Planning and the Geography of Great Britain" (Presidential Address, Section E).

At 10 a.m.—Prof. C. G. C. Chesters: "Fungal Friends and Foes" (Presidential Address, Section K, K*).

At 11.30 a.m.—Prof. H. J. Eysenck: "The Biological Basis of Criminal Behaviour" (Presidential Address, Section J).

At 11.30 a.m.—Sir Graham Sutton, C.B.E., F.R.S.: "The Resurgence of Interest in the Observational Sciences" (Presidential Address, Section X).

At 2.30 p.m.—Dr. N. Tinbergen, F.R.S.: "Why Do Animals Fight ?" (Young People's Lecture).

At 8 p.m.—Prof. W. J. G. Beynon: "The International Years of the Quiet Sun" (Evening Discourse).

Sunday, August 30

At 10.30 a.m.—Official Service in St. Mary's Church. Preacher: The Very Reverend the Dean of York, Canon Alan Richardson, M.A., D.D.

Monday, August 31

At 10 a.m.—Dr. W. Marshall: "The Exploration of Solids Using Thermal Neutrons" (Kelvin Lecture).

At 10 a.m.—Mr. W. H. Wilcockson: "Some Aspects of East African Vulcanology" (Presidential Address, Section C).

At 10 a.m.—Dr. C. A. Ralegh Radford: "History and Archæology" (Presidential Address, Section H).

At 11.30 a.m.—Prof. Lucy Mair: "How Small-scale Societies Change" (Presidential Address, Section N).

At 2.30 p.m.—Dr. H. A. Thomas: "Automation" (Young People's Lecture).

At 8 p.m.—Prof. A. S. Parkes: "Biological Aspects of the Population Explosion" (Evening Discourse).

Tuesday, September 1

At 2.30 p.m.—Dr. E. J. Ambrose: "Cells at Work" (Young People's Lecture).

Wednesday, September 2

At 10 a.m.—Dr. G. R. Coope: "Insect Populations in the Ice Age" (Darwin Lecture).

At 10 a.m.—Dr. V. B. Proudfoot: "Bringing Archæology to Life" (Lister Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Principal (normally national of the United Kingdom or the Republic of Ireland, with an honours degree in science or engineering, a recognized professional qualification, and extensive experience in industry, teaching and administration) of the Government Technical College, Enugu, Eastern Nigeria—The Council for Technical Education and Training for Overseas Countries, Eland House, Stag Place, London, S.W.1 (August 31).

Scientific Officer (graduate with a good honours degree in botany, biochemistry or chemistry, and preferably with research experience either in the physiology of higher plants or in plant metabolism)—The Director, Agricultural Research Council Unit of Plant Physiology, Imperial College of Science and Technology, London, S.W.7 (August 31).

Technicians (2) to assist with a programme of research into the effects of pathogenic bacteria on insects (one technician will be mainly concerned with the bacteriological aspects of the programme, and the other with the entomological aspects)—Prof. T. L. Bywater, Department of Agriculture, The University, Leeds, 2 (September 1).

Senior Research Assistant (graduate in science or veterinary science) to take part in research on respiratory disease in poultry in the Department of Veterinary Preventive Medicine at the Veterinary Field Station in Cheshire—The Registrar, The University, Liverpool, quoting Ref. CV/264 (September 5).

Research Assistant (either a physicist or an engineer with an interest in biology or a biologist with some knowledge of physics or engineering) at the Marine Science Laboratories, Menai Bridge, to work on the measurement of the forces of breaking waves on rocky shores—The Registrar, University College of North Wales, Bangor, North Wales (September 7).

Head (graduate, aged 30–45, with suitable university library experience) of the Periodicals Department—The Goldsmiths' Librarian, University of London Library, Senate House, Malet Street, London, W.C.1 (September 9).

Assistant Lecturer in Biochemistry in the Department of Physiology and Biochemistry, Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee, Scotland (September 12).

Fisheries Biologist (with a Ph.D. degree in biology, or postgraduate research experience of equivalent duration and standard, supported by satisfactory evidence of research ability, also postgraduate research experience in marine biology and/or fisheries biology, preferably with specialization in crustaceae, and a knowledge of statistics sufficient for biological research) in the Division of Fisheries and Oceanography, Commonwealth Scientific and Industrial Research Organization, Adelaide, South Australia—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 320/297 (September 12).

Research Officer (with a Ph.D. degree in physics or mathematics, or postgraduate research experience of equivalent standard and duration, supported by satisfactory evidence of research ability, and preferably an interest in flying) in the Division of Radiophysics, Commonwealth Scientific and Industrial Research Organization, Sydney, N.S.W., Australia, for interesting work in the field of cloud physics—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 780/364 (September 12).

Post-doctoral Fellows (with a Ph.D. in physics or electrical engineering or other appropriate field of postgraduate research) in Physics and Electrical Engineering in the Division of Applied Physics, Commonwealth Scientific and Industrial Research Organization, located in the grounds of Sydney University, Australia—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 750/315 (September 14).

Research Assistant (with a Ph.D. or honours degree in zoology or equivalent qualifications) to Dr. N. W. Runham, to work on reproduction in slugs—Dr. Runham, Department of Zoology, University College of North Wales, Bangor, North Wales (September 14).

Senior Professional Officer (with at least a B.Sc. degree with appropriate postgraduate experience, suitably qualified in one or more of the following fields: herpetology, ornithology or marine biology, and preferably some museum experience) at the Port Elizabeth Museum—The Chairman, Museum Board of Trustees, P.O. Box 1359, Port Elizabeth, South Africa (September 14).

Head of the Bacteriology Department; and an Assistant Bacteriologist—The Secretary, School of Agriculture, West Mains Road, Edinburgh, 9 (September 15).

Research Assistant (graduate in zoology and preferably some research experience in insect physiology or a related field) in Insect Pathology for work in connexion with a study of the bacterial pathogens of insects—The Registrar, The University, Leeds, 2 (September 15).

Assistant Lecturers (2) (candidates for the one post should have special interests in the evolutionary field studies, and for the other in physiology) in Zoology—The Registrar, The University, Manchester 13 (September 18).

Chair of Fuel Technology and Chemical Engineering—The Registrar, The University, Sheffield (September 19).

Lecturer (with qualifications in one of the appropriate basic sciences) in Dental Materials in the School of Dental Surgery—The Registrar, University of Liverpool, Liverpool, quoting Ref. CV/265/N (September 19).

Fisheries Research Biologists (2) (with at least an honours Bachelor's degree) with the Fisheries Research Board of Canada, one to be in charge of pelagic fish investigations (capelin, herring), and the other to assist in marine invertebrate investigations (squid, scallop, clam, oysters)—The Director, Fisheries Research Board of Canada, Biological Station, St. John's, Newfoundland, Canada (September 25).

Lecturer in the Chatterton Astronomy Department of the School of Physics—The Registrar, University of Sydney, Sydney, New South Wales, Australia (September 25).

Chair of Applied Mathematics—The Registrar, The University, Manchester 13 (September 30).

Chair of Genetics—The Registrar, The University, Leeds, 2 (September 30).

Director of the Electronic Computing Laboratory—The Registrar, The University, Leeds, 2 (September 30).

Entomologist (with a good honours degree in zoology, with special emphasis on entomology, and an interest in, and aptitude for, taxonomic research) in the Commonwealth Institute of Entomology Identification Service, which is accommodated at the British Museum (Natural History), to work on the Coleoptera—The Director, Commonwealth Institute of Entomology, 56 Queen's Gate, London, S.W.7 (September 30).

Lecturer/Senior Lecturer in Physics in the School of Physical Sciences of the University of Adelaide at Bedford Park—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and the Secretary for Bedford Park, University of Adelaide, Adelaide, South Australia (Australia, September 30).

Professorial Fellow, a Senior Fellow, and a Senior Research Fellow in the Department of Sociology, Research School of Social Sciences, Institute of Advanced Studies, Australian National University—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Chair of Biology at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 15).

Chair of Philosophy at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 15).

Assistant Lecturer or Lecturer in Experimental Physics—The Registrar, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex, marking envelope "Application".

Biochemist (Basic Grade) at Black Notley Hospital, Braintree, for duties under the direction of the Group Biochemist, to assist with the routine and development work of the Group Laboratories—The Group Secretary, St. Helena Group Hospital Management Committee, 14 Pope's Lane, Colchester, Essex.

Chair of Plasma Physics—The Registrar, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex, marking envelope "Confidential"..

Gassiot Research Fellows (2), one for research in seismology and the other for research in geomagnetism—The Secretary, Meteorological Office, London Road, Bracknell, Berkshire.

Herbicide Botanist (national of the United Kingdom or the Republic of Ireland with a degree in botany, preferably with postgraduate research experience) with the East African Common Services Organization, to undertake the botanical aspects of herbicidal and arboricidal work in East Africa with particular attention to weed pests in major East African crops—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, quoting Ref. RC 213/214/05.

Industrial Liaison Officer (man or woman with a good honours degree or equivalent in science or technology), to promote in local industry an appreciation and understanding of the value of technical, scientific and management development and to encourage the maximum use of the educational and advisory facilities of the College and of other local and national scientific and technical organizations—The Principal, Worcester Technical College, Deansway, Worcester.

Malacologist (national of the United Kingdom or the Republic of Ireland, with a first- or second-class honours degree in biology, and preferably appropriate relevant postgraduate research or experience) with the East African Common Services Organization, to study the aspects of snail life history, behaviour and distribution which affect their control by molluscicides and to study the effects of different molluscicides on snails—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/214/06.

Post-Doctoral Research Fellow (physical chemist or solid-state physicist with an interest and some experience in catalysis in gas/solid reacting systems) **in the Department of Chemical Engineering**—Dr. W. M. Crooks, Department of Chemical Engineering, The University of Birmingham, Birmingham 15, marking application "Research Fellow".

Professor of Anatomy and **Head of the Department**—The Dean, Faculty of Medicine, University of Manitoba, Cor. Bannatyne and Emily Streets, Winnipeg, Manitoba, Canada.

Protein Chemist to work on antibodies and antibody-like substances; a **Protein Chemist** (interested in pollen, mould and tissue antigens); a **Chemist** or **Biochemist** (B.Sc., Ph.D. or experienced technician) to take charge of fluorescent microscopy, mainly in connexion with work on antibodies; and a **Physical Chemist** to work mainly with microcell electrophoresis apparatus, in the Immunochemistry Unit for Research in Cancer and Allergy (Department of Bacteriology)—The Registrar, The University of Liverpool, Liverpool, 2, quoting Ref. CV/262/N.

Research Student (with a good honours degree in physics) **with the Spectroscopy Group in the Department of Physics**, for work on radiation characteristics of plasmas and spectra of highly ionized atomic species—Dr. W. R. S. Garton, Physics Department, Imperial College of Science and Technology, London, S.W.7.

Senior Research Associate in the School of Chemistry for research into reaction mechanisms in boron chemistry—The Registrar, The University, Newcastle upon Tyne.

Technical Assistant (with an ordinary degree, H.N.C. or equivalent qualification in chemistry) **in the Robert Robinson Laboratories, Department of Organic Chemistry**, to join a group investigating fungal biosynthesis—The Registrar, The University, Liverpool, 3, quoting Ref. CV/267/N.

SCIENCE AND BEHAVIOUR

THE scientific study of human behaviour has been a recurrent theme in presidential addresses to the British Association during the past decade. In 1954, Lord Adrian, clearly perturbed by the implications of modern science for man and society, made a strong plea for the furtherance of the human and social sciences. In 1959, Sir James Gray reminded scientists that humanists have no monopoly of the maxim that the proper study of mankind is man. In 1961, Sir Wilfrid le Gros Clark, speaking on the theme of the humanity of man, was no less insistent on the need for fuller understanding of the springs of human action. While this concern may be ascribed in part to the growth and promise of what have come to be called the behavioural sciences, there is no doubt that it also reflects the reaction of many scientists to contemporary hazards, particularly the danger of all-out nuclear war. As Sir Wilfrid sombrely enquired: "Can the human species avoid at least partial extinction by the misapplication of its own ingenuity ?".

In his address on *Science and Behaviour* (see p. 943 of this issue), Lord Brain to some extent follows in the footsteps of his predecessors. Like Sir Wilfrid le Gros Clark, he lays stress on the comparative and physiological approach to the problems of behaviour. Like Lord Adrian, he shows himself well aware of the special problems created by man's evolutionary development and the importance of taking into account the social context of his activities. But he is much less evidently concerned with the prospect of imminent annihilation. As he sees it, the dangers ahead of us stem from the "frozen emotional attitudes of the past" rather than the lurid perils of the future. He advises us how to live with science rather than how not to die from it.

In his attempt to present a biological view of behaviour —including our own—Lord Brain draws together evidence from a variety of biological disciplines, including ethology, comparative neurology and experimental psychology. He also touches on criminology and the social sciences. Although only too well aware that "to try to give such a satellite view is to court attack from those over whose territory one flies", Lord Brain's astronautical essay is unlikely to provide a target for the specialist anti-missile missile. Indeed, workers in the behavioural sciences everywhere will derive much encouragement from his thoughtful survey.

Quite properly, Lord Brain takes his departure from the study of the lower organisms. As he rightly reminds us, animals with comparatively simple nervous systems may exhibit quite complex behaviour, but that in studying its properties it is much easier than in the case of man to isolate the factors involved. This leads him to consider the selective responses, often surprisingly elaborate, shown by insects and birds in their food-seeking and reproductive activities. Although he gives some consideration to the nervous mechanisms on which these patterns of behaviour depend, it is perhaps a pity that he does not discuss the ways in which more primitive nervous systems differ from those of the higher animals. For example, it now seems clear that the possibilities of integration are much more limited in the insect nervous system than in that of vertebrates owing to the inherent limitations of the insect neurone as an integrating unit. From this it follows that the nervous mechanisms which have been evolved to cope with essentially similar problems of adaptation may vary widely at different levels of the evolutionary hierarchy.

In turning to the behaviour of higher vertebrates, Lord Brain takes note of recent physiological work on the mechanisms of sensory discrimination in the receptor organs and the brain. This is already beginning to give us a fairly detailed picture of the ways in which sensory information vital to adaptive behaviour is taken in, coded and processed in the receptor systems. But he appreciates, too, that behaviour depends in large measure on endogenous factors, commonly referred to as instincts or drives. This leads him to consider the part played by certain phylogenetically primitive areas of the forebrain in the control of instinct and emotion. Here he touches on an important and rapidly advancing area of physiological knowledge, in which the classical techniques of neurophysiology have been fruitfully combined with the methods of experimental psychology. Indeed, the steady growth of interdisciplinary research in this field has already thrown much light on the brain envisaged as the instrument of behaviour.

Ever since Darwin, it has been traditional to enquire in what respects man most closely resembles his animal relatives. Lord Brain turns the question around. In what respects, he asks, do human beings, as animals, differ from other animals ? The uniqueness of man, in Lord Brain's view, lies in his outstanding learning capacity and, more significantly, in his possession of language. (Wisely, perhaps, he eschews the question of intelligence.) These evolutionary advances he relates to the outstanding development of the major regions of the human neocortex. Although the existence of a correlation between brain size and intellectual capacity has been accepted since the time of Gall, it must be admitted that its nature is still almost wholly obscure. We still do not know, for example, why the left temporal lobe of the human brain can sustain speech while that of the chimpanzee cannot. Here considerations of relative size alone are unlikely to be decisive. Nor do we yet know for certain whether human intelligence depends on circumscribed areas of the brain cortex or whether it is principally due to a mass-action factor, as Lashley and others have surmised. Until human cerebral organization is far better understood than it is at present, the biological uniqueness of man will remain an enigma.

It is the evolution of language, Lord Brain believes, allied with the growth of self-consciousness, that provides the impetus to seek the explanation of our own behaviour. Can man explain himself ? Is there a science of human behaviour ? Experimental psychology, which has now been in existence for almost a century, claims to provide such a science. Yet it has so far failed to produce a coherent body of explanation of the kind which might reasonably be expected of a scientific discipline. Nevertheless, Lord Brain appreciates the contribution which experimental psychology has made to our understanding of limited segments of human activity, for example, the study of sensory-motor skill. Where psychology has so far failed has been in the development of truly quantitative methods for the study of complex mental processes. The measurement of intelligence is a case in point. As Lord Brain points out, it is far from clear what the conventional intelligence tests are measuring or what interpretation should be placed on the results. There is, he suggests, a great need for fruitful hypotheses to direct genuine experimental attack on the problem of mental ability. This need is perhaps even greater in the sphere of emotion and temperament. Nevertheless, Lord Brain does not contest the value of psychological enquiry, even where woefully inexact. He has even a good word for Freud.

But experimental psychology can scarcely compass man in his relations with society. Here Lord Brain accepts the claim of the social sciences to study man scientifically, but is under no illusions as regards the difficulty of the task. This he illustrates vividly with regard to recent studies of crime and its causes, which might appear to be scientific in little more than name. Lord Brain suggests that in the social sciences generally we need not only more and better observations but more and better hypotheses. One might suggest that we also need more and better men. But how are we to find them ? At the present time, the social sciences tend to attract arts men without basic scientific training or scientists who have failed to make their mark in a more conventional field of scientific enquiry. How are we to attract to the social sciences men of the calibre of Darwin, Rutherford or Freud ? Money, encouragement and facilities are not enough. A positive lead must be given to find, educate and hold the right kind of men.

In conclusion, Lord Brain is led to express some general views of the proper use of our human resources in an age of rapidly expanding industrial technology. He urges that the speed of modern industrial development makes it essential that we should attempt to forecast the social changes which radical changes in technology will inevitably bring about: and this, in turn, will depend largely on our fostering, through education in the broadest sense, new attitudes to the rapidly changing social environment which science is creating. This problem is real and important. Actions may be changed more rapidly than attitudes, and every change in technology is liable to bring about some change in long-established concepts of status and responsibility. If individuals are unprepared for social change, serious loss in personal security and social stability may ensue. Education, even in the wide sense advocated by Lord Brain, is not enough. We need also much more serious study of human reaction to technological change and its impact on social structure. This, perhaps, is the most urgent challenge to the social sciences and the real lesson of Lord Brain's address.

"AND NEAR A THOUSAND TABLES PINED AND WANTED FOOD"

Man Must Eat

By Sir William Slater. Pp. ix+112. (Chicago and London : The University of Chicago Press, 1964.) 28*s*.

MAN Must Eat deals with the age-long problem of increasing the food supply to keep pace with the increasing population. It consists of four lectures delivered in the University of Chicago. These are augmented for publication with an introduction giving a general account of the main aspects of the problem.

The subjects of the lectures are on the means of food production, food processing, the problem in the developing countries, and the effect on mankind of the fall-out from nuclear tests. For those engaged in food research the most interesting are probably those on food processing and the fall-out from nuclear tests. These are excellent reviews of recent advances in knowledge in these subjects.

The lecture on food production in the developing countries shows the difficulties and indeed the possible dangers of giving technical aid on food production. Some of the technicians sent out to the food-deficit countries seem to think that all that is needed to modernize their agriculture is to give the local inhabitants the Western 'know-how'. Few of them have the 'know-how' needed for soil and climatic conditions and social and economic systems different from the Western temperate zone countries, and on tropical crops of which Western experts have little experience. Further, they are apt to forget that some of the countries, like India, for example, have colleges of agriculture and research institutes with well-informed senior officials, many of whom are trained in Western universities. They know as much about the principles of agriculture as foreign experts and, in addition, know the difficult and complex conditions to which modern methods must be applied. As Sir William Slater points out, the main difficulty is the lack of local industries to produce the fertilizers, equipment and other things needed for increasing production, and the foreign credits to import them.

Looking to the future, Sir William estimates that by the end of the present century, that is, only thirty-six years ahead, the population of Britain will reach 70 million—an appalling thought for the already crowded Islands. He also estimates that home food production can be increased by only about 40 per cent. So, with her increasing population, Britain will continue to depend on importing about one-third of the food she consumes. The population of the United States will also increase so much that by the end of the century it will have no surplus to export.

This raises the problem of where Britain can find her food imports. It will not be from the food deficit countries where, with all the technical and financial aid they receive, increased production can do little more than provide for the increase in population. During 1962–63 it failed to do even that, with the result that the amount of food per head of the world population actually fell. Second only to war, the accelerating growth of population, with a possible food shortage, is the most serious threat to Western civilization. It warrants more attention from leading politicians than the attempt to put a man on the Moon, or even which political party is going to win the next election.

It is not certain, however, that the threatened world food crisis will occur. The present rate of increase of population may begin to slow down as has already occurred in a few countries, notably Japan, where the number of births fell from 2,697,00 in 1949 to 1,607,000 in 1962. If the new oral contraceptive could be produced in sufficient quantities and brought within the purchasing power of the poorest, it may slow down the growth of population and the alarming estimated increase in population may never be reached.

Sir William warns us that it will be difficult, if not impos-ible, to provide sufficient food for the rapidly growing population. That is certainly true under present political and economic conditions. If, however, all Governments would co-operate in a world scheme for the production and distribution of goods to eliminate hunger from the world, then, with modern agricultural and engineering science, sufficient could be produced even though the population increased at its present rate for another hundred years.

This book on food problems by an authority of international repute deserves to be studied by scientists and also by Governments and their officials dealing with the national and international aspects of food production.

BOYD-ORR

THE COMPUTOR IN SEARCH OF OPTICAL NEURONES

Optical Processing of Information

Edited by Donald K. Pollock, Charles J. Koester and James T. Tippett. Pp. x + 286. (Baltimore: Spartan Books, Inc.; London: Cleaver-Hume Press, 1963.) 60*s*.

OPTICAL Processing of Information forms the proceedings of a conference of the 'cross-fertilizing' type, held in October 1962 under the sponsorship of the U.S. Office of Naval Research and the American Optical Company, at Washington. The purpose was to bring modern optical devices to the knowledge of computor experts, with a view to bigger, better and faster computors. Somewhat surprisingly, the first of the nineteen speakers, Prof. H. M. Teager of the Massachusetts Institute of Technology, poured cold water on these hopes by showing very convincingly that optical elements such as fibres, lasers, photoconductors, have, at most, a very slender chance of competing with already existing electrical components, such as tunnel diodes and thin films. This did not prevent the conference from going on cheerfully for another eighteen lectures. One cannot deny that these present a great deal of stimulating and even exciting material to the inventive mind; the sort of mind for which the difficulty of ever reaching the final objective is a challenge rather than a discouragement.

The past ten years have produced two outstanding optical developments; fibre optics and lasers. Fibre bundles, one-half inch in diameter, can contain one million fibres, and can conduct a picture with about 50 lines/mm over several yards, if required, over a very tortuous path. In fact, the information capacity of such a bundle is better than one logon per fibre, because more than a dozen orthogonal modes can be propagated in each (O'Brien, Snitzer, Koester of the American Optical Company). An interesting, unorthodox application of fibres is described by R. D. Hawkins in an enthusiastic article, perhaps a little too untainted by theory. Fibres are assembled into a brush with bristles of various lengths, and are made to vibrate by a complex sound. They reveal the spectrum of the sound by their amplitude pattern, a principle well known since the time of Frahm. What is novel is the idea of selecting speech sounds, even words, for recognition by putting a photographic plate in front of the fibres, exposed to the pattern which is to be recognized, which then serves as a selective mask. Somewhat more sophisticated pattern recognition principles are described in an article on the 'Perceptron' by Babcock, Friend and Heggs, but the results are somewhat disappointing in relation to the enormous gadgetry, and appear to be inferior to those obtained by W. K. Taylor (University College, London) by simpler means. André Maréchal (Paris) summarizes the interesting work of the French school on the improvement of images by optical filtering, that is to say, operating on the Fourier transform of the picture; and this is completed in an article by El-Sum, who has made important improvements in the double-diffraction method introduced by me fifteen years ago.

The rest of the contributions are mostly devoted to the production of light by lasers, and methods for its modulation. At the time of the conference, the neodymium–barium glass laser was the great novelty, and the gallium arsenide laser was just making its first appearance. The weakness of the laser schemes is not only in their inefficiency but also in the near-impossibility of devising really fast methods of modulation for what is essentially a high-*Q* device.

This book will be useful to all those who would like to keep up with the development of optical art, and for anybody who wants a vivid picture of the way in which the old art of invention is carried on in the modern world.

D. Gabor

EARTHQUAKES AND EARTH STRUCTURE

Earthquakes and Earth Structure

By John H. Hodgson. Pp. ix + 166. (Englewood Cliffs, N.J., and London: Prentice-Hall, 1964.) 24*s*.

DR. J. H. HODGSON, chief of the Division of Seismology, Dominion Observatory, Ottawa, is the famous son of a famous father—Ernest A. Hodgson. That he has written this modest book for the non-specialist should not only help to ensure that any non-specialist will henceforth be interested in seismology, but also that seismology will attract more scientists to its disciplines and more people in general to its support.

After the introduction, *Earthquakes and Earth Structure* is divided into four parts, the first two being approximately of equal length, and the final two each about half the length of the first. The first section is descriptive of nine well-chosen shocks, together with a selection of isolated interesting occurrences due to earthquakes. The second section is concerned with the observation of earthquakes and earth structure (seismology), the third with statistics, geography and causes, and the final one with seismic regionalization, earthquake engineering and international co-operation.

Of the earthquakes chosen for description, the earliest is the New Madrid series of 1811–12, and the most recent the swarm in Chile in 1960. This 1960 swarm in Chile began on May 21, the main shock coming about 11 min after 3 o'clock in the afternoon of the second day. The motion of this earthquake was smooth and rolling with smaller oscillations imposed on it, the maximum intensity being felt in the coastal areas from Puerto Saavedra to Isla Chiloé and along the Reloncavi fault in the Chilean Lakes region. There were thousands of landslides and seiches in the lakes with amplitudes up to 3 ft. and in the region silty clay flowed like water. On the Isla Mocha there was a land elevation of 7 ft., so that the foundations of the dock became clear of water. Near Valdivia there was a depression of the land so that salt water now floods land up-river from the city. The volcano Puyehue, dormant since 1905, erupted and sent a cloud of ash and steam 20,000 ft. into the air.

The principal shock produced one of the most spectacular tsunamis on record. Some minutes after the shock the sea receded from the coast, returning about 10 min later with great speed and with wave heights of as much as 20 ft. The periodic retreat and advance of the sea continued throughout the afternoon. In Puerto Saavedra, debris was later found nearly 2 miles inland. This tsunami crossed the Pacific Ocean, causing coastal damage and casualties. In Japan it arrived more than 22 h after the time of the earthquake that caused it, attaining a height of some 12 ft., and doing much damage. 180 Japanese died as a result of this tsunami. Tremendous damage was done in Chile by the earthquake, by permanent ground displacements at the time, and by the tsunami. Many were killed and injured and the economy of the area suffered a blow from which it will take years to recover.

Considerations such as these, Dr. Hodgson asserts in his book, make it imperative to do something about the matter. Two important ways, apart from pure seismological research, are opening up in many countries throughout the world. The first is called 'seismic regionalization', and the second 'earthquake engineering'.

'Seismic regionalization' is a term first introduced by the Russian seismologists. Seismic regionalization maps are usually contoured to show maximum earthquake intensity likely to be encountered at each point on the map. Such estimates are extrapolations based on all available evidence, present geo-tectonic as well as historical-seismic. Prof. V. V. Beloussov, with the assistance of the European Seismological Commission, has produced the first draft of a seismo-tectonic map of Europe, and other maps of a somewhat similar character have been produced for other countries and regions of the world. Dr. Hodgson gives maps for Canada and the United States in his book.

For engineers dealing with earthquake-resistant design, a knowledge of the maximum earthquake intensity likely to be encountered in any locality is only a beginning. Strain seismographs can indicate present trends, strong motion seismographs can record accelerations and periods, and from shaking-table experiments much can be learned since the shaking may now be made to simulate actual earth movement during the earthquake for which seismograms are available. In some areas of the world building codes are absolutely essential. Moreover, since the advent of atomic power stations into areas likely to be affected by earthquakes, the problem has become much more acute. In recent years in Britain a seismic engineering group has been formed. This would have delighted John Milne, the 'founder' of British seismology and, through the British Association for the Advancement of Science, the originator of the project of a world-wide network of unified seismograph stations; for Milne was a British professor of engineering in Japan, turned seismologist. Dr. Hodgson in his book deals with the North American attack on these problems.

Dr. Hodgson's book will prove a most valuable introduction to the observation of earthquakes for all who wish for a non-mathematical approach. It cannot fail to be interesting and informative, and the only drawback in Britain is the price; 24*s*. is rather expensive for a paper-back of 175 pages. E. TILLOTSON

A CHAPTER OF CHEMISTRY

Man-Made Transuranium Elements

By Prof. Glenn T. Seaborg. (Foundations of Modern General Chemistry Series.) Pp. viii + 120. (Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963.) 12*s*. paper; 32*s*. cloth.

NO part of chemistry, not even a paragraph, is ever complete; but this important chapter has now reached a stage where further developments can be expected to be more in the nature of refinements to the style, than exciting new changes or additions to the text.

Most books are written for a readily identifiable readership, first- and second-year university texts, authoritative monographs for research workers and a number of other clearly defined categories. It is pleasant to read a scientific work that avoids this classification. *Man-Made Transuranium Elements* was written as a consequence of the author's interest in the Chemical Educational Material Study Group in California. One presumes that it is intended, in part, for the more gifted secondary or high-school student. Although it would be surprising if many such students, even in California, could really understand everything in the book, it is certainly true that they would both profit from and enjoy reading it.

The author and the subject are so related that the book has a strongly autobiographical flavour. Never obtrusive, these touches heighten the reality of the historical sequences in the book and convey much of the excitement that was felt during many of these remarkable discoveries.

The story is unique; eleven man-made elements produced and identified in twenty-odd years, many of these in Prof. Seaborg's laboratory. But the proliferation of the elements, though interesting, is not the most important scientific aspect of these achievements. Now that one begins to read this chapter in the context of the rest of the developments in chemistry, it is, perhaps, possible to begin to pick out the most significant features.

First, the key to the identification of the later members of the group, the demonstration that these elements constitute a new series in which the 5 *f* orbitals are being filled. Such a series had long been predicted, even in such details as its differences from the lanthanide elements; but, as ever, the facts, while broadly confirming these predictions, threw up a host of new problems. Some of these, such as the unusual crystal structures and properties of the elemental forms of these metallic elements, are still unresolved.

The earlier investigations of the first five or six transuranic elements were a triumph for microchemical techniques. The tetrad, uranium, neptunium, plutonium and americium, with their several valencies has provided inorganic chemistry with a rich field of investigation for many years to come. The difficulty of the separation of these elements, especially those of the highest atomic number, has led directly to a much deeper knowledge of the processes of ion exchange and solvent extraction. Indeed, it is clear that, but for the close analogy between the ion-exchange behaviour of the actinide and lanthanide elements, it is unlikely that the elements of greater atomic number than curium would have been characterized so quickly. Present-day knowledge of their chemistry amounts to little more than their ion-exchange characteristics.

Besides these important purely chemical results, the production and investigation of the transuranium elements have yielded a rich reward of nuclear chemical information. A large part of our knowledge of fission derives from observations of isotopes of these elements.

The accumulation of a substantial body of fairly reliable data on the nuclear characteristics of the numerous isotopes of these elements revealed a number of these systematic features of nuclear stability, and this provided one of the lines of evidence on which our knowledge of nuclear forces has developed.

Some years ago, the present director of the Atomic Energy Research Establishment, Dr. R. Spence, proposed to me a measure of the importance of developments in natural science which is easily applied and generally reliable. The really important developments are those that, within two or three years, demand inclusion in the undergraduate courses. By this yardstick, this chapter of chemistry does indeed include a number of developments of fundamental importance. A. G. MADDOCK

INSTRUMENTATION FOR CHEMICAL ANALYSIS

Analysis Instrumentation–1963

Edited by Dr. L. Fowler, R. D. Eanes, and T. J. Kehoe. (Proceedings of the Ninth National Analysis Instrumentation Symposium held April 29–May 1, 1963, at Houston, Texas.) Pp. x + 261. (Pittsburgh, Pa.: Instrument Society of America, 1963. Distributed by Plenum Press, New York.) 12.50 dollars.

AS the bibliographic particulars indicate, this volume contains papers read at a symposium, and it follows the usual pattern, covering a very wide field. Unlike the *Proceedings* of earlier symposia of this series, the book is bound in hard covers.

There are thirty individual papers grouped under six headings:

"Keynote Session—Analysis Instrumentation Today" deals with the present status of analysis instrumentation from the point of view of the manufacturer, user and developer, and is discursive and non-detailed. Three pages devoted to humorous and apt cartoons enliven this section.

"Dynamics of Analysis Instruments" is concerned with detailed design of instruments for the control of dynamic industrial processes, for example, optimum settings for a cigarette machine and a conductivity bridge for tests on extraction apparatus and continuous flow empty and packed columns.

"Problems of Analyzer Applications" includes the calibration of gas monitors and process gas chromatographs and the application of flame ionization chromatography to raw motor-car exhaust gases and to the analysis of paraffin waxes. Space research is catered for by a paper on the design of a lunar gas chromatograph.

"Laboratory Instrumentation" has an interesting paper dealing with polymer molecular weight measurement by gel permeation chromatography: a potentiometric method detects as little as 2·5 p.p.m. of chloride in various salts: peroxyacyl nitrates, 'smog' air pollutants, are determined by gas chromatography. Other papers are concerned with instrument demonstrations and processing analytical data.

In the section dealing with "Electrochemical and Chemical Methods" we find described a sensitive instrument for continuous measurement of temperature changes on mixing two liquids, for example, dilute solutions of citric acid and sodium hydroxide. An all solid-state *p*H meter, a new method for instrumenting square wave polarography and an autoanalyser for the determination of chemical oxygen demand in water are also described. Two papers are concerned with the measurement of moisture, one based on the use of microwaves and one on a dielectric system.

"Radiation Methods of Analysis" contains two papers concerned with the use of infra-red in the determination of gases and toxic vapours: infra-red absorption data for 320 gases and vapours are tabulated. Lunar exploration receives attention in a paper describing neutron activation methods for compositional studies and another paper relates to the use of charged particles for the bombardment. Two instruments are described, a gamma-ray density gauge and a spectrodiffractometer, the latter an instrument for chemical analysis by both X-ray diffraction and emission.

With such a mass of information, detailed comment in a review is not possible.

The book should be of interest to all concerned with instrumental methods.

C. O. Harvey

NORTH AMERICAN ECOLOGY

The Ecology of North America

By Victor E. Shelford. Pp. xxii + 610. (Urbana: University of Illinois Press, 1963.) 10.00 dollars.

THIS large, well-illustrated book is the culmination of a lifetime of ecological research by Prof. Shelford, aided by numerous students, and is based on many field expeditions throughout North America. By combining the observations of early travellers with surveys of semi-natural areas, Prof. Shelford is able to attempt to describe the ecological situation in North America during the sixteenth century before the arrival of European settlers. He has succeeded remarkably well in this formidable task, but not everyone will agree with his description of primeval North America. It is strange, for example, that the effects of windblow receive scant attention, yet American ecologists at Yale and Harvard have emphasized that uprooting of forest trees by wind was of widespread occurrence, with tornadoes regularly cutting swathes through the forest sometimes over two kilometres wide. The effects of successive, ancient windthrows can be traced in the irregular forest floor of humps and pits and in the complex soil morphology that has resulted from repeated overturnings of the soil layers.

The Ecology of North America contains nineteen chapters, the first of which deals with the definition of ecological terms and concepts used in the book. Some of these, such as permeants and influents, are not generally used and are of doubtful value. Each of the remaining eighteen chapters is devoted to the description of a major ecological community, which range from the tundra biome of the north to the tropical rain forest of the south. The major communities are subdivided into regions and seral stages of development. A large list of literature cited is given but unfortunately many modern investigations, such as the description of the vegetation of Wisconsin by Curtis, are not included. Excellent locality and species indexes are provided but no general index, so that it is difficult to obtain readily a picture of the influence of fire or of Indians.

In describing the ecological communities, Shelford expertly brings together a great amount of information on the characteristic species of plants and animals present and also on their numbers and interrelationships at different seasons of the year. This information is set against the background of topography, soil, climate and human influence. The careful integration of knowledge gained from different disciplines provides an excellent insight into the complexity of natural biological situations and of the virtues of comprehensive investigations.

Undoubtedly the book will be invaluable to conservationists and to anyone concerned with management of natural resources, for it provides a unique historical perspective against which to view past and future developments in North America. It also serves to direct attention to the inadequacy of our knowledge of the interrelations between plants and animals and of the quantitative aspects of community dynamics. These deficiencies need to be remedied if ecologists are to contribute significantly to schemes of land use and to understand the impact of modern technology on Nature and natural resources.

THE BIOSPHERE

Animal Worlds

By Marston Bates. Pp. 316 + plates. (London: Thomas Nelson and Sons, Ltd., 1963.) 84*s*.

ANIMAL WORLDS is an introduction to natural history by way of ecology. It makes no attempt at a systematic description of the animal kingdom but deals in turn with many different environments, their floras and faunas. Marston Bates has travelled widely and is well qualified to write on natural history from this angle; he writes skilfully and has produced a lively and interesting volume that will be appreciated both by the layman and the professional zoologist. In spite of the vast range of the subject, its salient points are covered and much illuminating detail is included within the moderate space of more than three hundred pages.

The ecological treatment gives scope for the consideration of many aspects of animal life, including not only the direct reaction of animals to the physical environment, but also their physiology, behaviour, special adaptations, migrations, breeding habits, relationship to other species of animals and to plants, to mention only a few. The result is a real natural history of the biosphere in which the wood is not obscured by the trees and which gives a good insight into the complicated relations between animals and their physical and biological surroundings. As Bates remarks in the foreword, a survey such as this is necessarily selective from the great mass of material available, but his selections are judicious and very much to the point.

The final three chapters deal with the relationships between man and the other animals, with domestication, extermination, parasites, pests and pets. Much of the surface of the Earth is rapidly being changed by man's activities; the changes eliminate some species of animals but provide favourable conditions for others which are able to reach a biological equilibrium. The important exception, which has not yet become extinct nor reached a state of equilibrium with the environment, is man himself. If he does not apply his knowledge of biology to solving his own biological problems on a very large scale without loss of time, he may well come to realize the truth of the sun-dial motto, "It is later than you think".

The style of this book, written and first published in the United States, naturally has an American flavour. The editing of this British edition is, however, irregular—the caption of the picture illustrating the capercaille gives the bird's name as 'wood grouse', and that of a skua has not been translated from the American 'jaeger'. The name 'cockroach' appears in all its horrid nakedness alongside 'roach', emasculated in deference to American prudery.

The beautiful photographic illustrations, many of them in colour, add greatly to the attractiveness of the book. But the author has suffered, as have many others, from the photographs having been collected, as he acknowledges, by the editors, who presumably have supplied the captions which unfortunately contain some errors. The 'living zooplankton' is manifestly a preserved dead sample; the nesting 'fulmars' are herring gulls; the Brazilian 'horned frogs' are toads and are not as stated 'strictly aquatic'; the flamingos in Lake Nakuru are feeding on surface plankton, not "reaching down into the mud"; the Amazonian tapir is not an "odd relative of the elephant"; the 'topi' in Nairobi Park are not topi (*Damaliscus*) but kongoni (*Alcelaphus*) . . . and so on. It is a pity that these blemishes have been allowed to disfigure an otherwise splendid and fascinating book.

L. HARRISON MATTHEWS

AT THE TURN OF A TAP

Salt Water Purification

By Prof. K. S. Spiegler. Pp. ix + 167. (New York and London: John Wiley and Sons, Inc., 1962.) 57*s*.

THE inhabitants of the British Isles are apt to take for granted the supply of fresh water on tap and are prone to complain about the excessive rainfall. Water of drinking quality is generally available for all domestic purposes and, at slight extra charge, for car-washing and garden watering. Probably ten times as much water as is thus consumed is used in addition for irrigation and for industrial purposes to provide us with the needs of an industrial society. It is therefore not surprising that Manchester, with its high concentration of industry, is forced, despite its reputedly high rainfall, to seek additional supplies of water from Wales and the Lake District. The fact that the rich farm lands of Essex would benefit from the equivalent of another eight inches of rainfall is probably less well known. The general shortage of water in this area may indeed limit the growth of new towns there. There is an evident need to conserve water by persuading industry of the necessity of recovering and re-using its process and rinse waters and by reducing to a minimum the pollution of the rivers and lakes from which supplies are drawn.

If conservation of water is important in Britain, it is still more vital for the arid areas of the world, which are being opened up in the search for natural gas, oil, and minerals, and in response to the ever-growing pressure of world population. Some of these areas are not far removed from the sea, but, although the oceans represent a vast reservoir of water, it is too salt to drink since it contains about seven times as much salt as can generally be tolerated for this purpose. At the same time, the rainfall which supplies our fresh water has resulted almost entirely from the evaporation of water from the sea and its subsequent condensation in the cooler parts of the atmosphere to form clouds. In seeking to supplement his supplies of fresh water in the arid regions, man has inevitably turned to local brackish waters or to sea-water as the source of supply. However, while the random supply of rain water at the whim of Nature costs us nothing, apart from impoundment and distribution, the separation of fresh water from salt water involves an irreducible minimum of energy, which is exceeded by a substantial margin in practice, thus making the process a doubtful economic proposition. Only where the need for fresh water is the overriding consideration, as in parts of the Persian Gulf area, Israel, or Libya, or where the problem of storage is the decisive factor, as in Guernsey, has much use been made of salt water sources.

Prof. Spiegler's book *Salt Water Purification* is concerned not only with the problems outlined here, and to an extent which reveals his concern for humanity, but also with the ingenuity that has been brought to bear on their solution. In this latter aspect he reveals the clarity of thought and exposition which characterizes him as a scientist. His aim of providing "an understanding of the essentials of salt water purification in simple terms for all those interested in the field" has surely been achieved. The scientist or engineer will certainly find in the book a useful overall survey of the problem, while the statesman or economist will find in it an adequate background to enable him to appreciate the fundamental principles involved and a guide to the jargon of the technologist. The text, diagrams, and tables are easy to follow and should not present any great difficulties to the layman.

The first three chapters deal with the basic problems of salt water purification, including the underlying thermodynamic considerations. In the fourth chapter the problem of scale-formation, which occurs in most of the distillation methods and in electrodialysis, is discussed in detail. Of the four chapters which follow, one is devoted to each of the methods of distillation (including multiple effect, flash, vapour compression, and solar), electrodialysis, freezing, and ion-exchange. In each case the practical considerations, the advantages, and the disadvantages are fully discussed. Miscellaneous methods, including solvent extraction, ultrafiltration, osmionis, and critical pressure distillation which, although feasible on a laboratory scale, have not for various reasons been felt of sufficient promise to justify large-scale tests, are briefly discussed in chapter nine. The final chapter of summary and conclusions underlines the problems of assessing the relative costs, not only of producing fresh water from salt as compared with the transportation of the former from the nearest available source, but also of the various processes of desalting. So much depends on the scale of operation and on purely local considerations such as the sources of energy available. An appendix gives a rather more detailed treatment of energy considerations and a table of unit conversions, and there is a useful bibliography.

Frequent references are made in the book to the extensive contributions to this field of the Office of Saline Water, U.S. Department of the Interior. Those who are surprised at the relatively few references to British work may be interested to read the report of a lecture given recently by Dr. Miller of the Water Research Association to the Royal Society of Arts (*J. Roy. Soc. Arts*, 112, 491; 1964) in conjunction with Prof. Spiegler's book.

I myself hope that many others will read this book with as much interest as I have done. Concern for our fellow men should prompt our interest in the problems of the arid regions, but the general problems of water conservation are coming even closer to our doorstep.

The importance of this topic is further underlined by the report (*The Times*, June 25) of the United States and Soviet Governments' joint research project.

J. E. SALMON

Selected Papers of Ernst Georg Pringsheim

Edited and with a preface by Prof. C. B. van Niel. Pp. ix + 331. (Published for the Institute of Microbiology. Distributed by Rutgers University Press, New Brunswick, New Jersey, 1963.) 6.50 dollars.

MICROBIOLOGY is now in a transitional stage in which the ideas of the older microbiologists, based as they were on morphology and simple physiology, have given way to those of the biochemist, the geneticist, and the statistician. Pringsheim belongs to the old school, and to read these collected papers is like turning back from the pages of a modern biology to a treatise on old-fashioned natural history. Here are arguments and discussions based almost entirely on morphology, and there is a wonderful sense of simplicity about all the micro-organisms discussed in these papers. That they are borderline forms between the blue-green algae and the bacteria is not disputed, but there is a remarkable—some might think commendable—lack of evidence of the kind we now expect and demand of our taxonomists.

This is a group of micro-organisms about which most of us know little or nothing, and they are described by a master of technique who has had the patience and pertinacity to make of them a most detailed study; here he tells us in simple terms what he has learnt in this work of a lifetime. They are probably not economically important organisms, they do not cause infections or poison food, but they are the happy hunting ground of an almost extinct kind of naturalist-microbiologist. This book is refreshing, for it shows how far we have come in the past few decades; it is stimulating, for it shows how right we are to question all the convictions of the classical taxonomists.

These papers show what has been done by good technique and careful observation; they should serve as object lessons to microbiologists to renew acquaintance with the light microscope and the simpler tools of their trade. With the advantage of hindsight we may be tempted to judge Pringsheim's opinions as those of a dogmatic teacher upbraiding the enquiring and unbelieving pupil. He is impatient with Buchanan and intolerant of opinions such as Pijper's on the mechanism of bacterial motility, but the simplicity of the arguments is like manna to the genetically and computer-sotted mind of the modern taxonomist.

S. T. Cowan

The Formation of Wood in Forest Trees

The Second Symposium held under the Auspices of the Maria Moors Cabot Foundation for Botanical Research, Harvard Forest, April 1963. Edited by Martin H. Zimmermann. Pp. xv + 562. (New York and London: Academic Press, 1964.) 114*s*. 6*d*.

"THE Physiology of Forest Trees" was the theme of the first Cabot Foundation symposium, and the second, held six years later in 1963, took as its topic "The Formation of Wood in Forest Trees", thus continuing the general subject of fundamental problems of tree growth. The papers and edited discussions are now available in this excellent publication.

In recent years, much research has gone into the various processes which are associated with the formation of wood and many of the results and some of the theories of this rather complicated subject have been dealt with by the 28 contributors from North and South America, Europe and Australasia. The papers are grouped into four parts. Part 1 is concerned with the cambium and its derivatives. Too often the cambium is treated in rather general terms, but it is evident that we need to know more about its rate of division during the growing season to prove or disprove certain theories associated with it. Phloem, one of its derivatives, becomes in its secondary state bark, but the characteristics of a particular bark are determined not only by the structure and development of the phloem but also by the structure of the periderm and by the timing, depth and frequency of its initiation in the bark. Advances in electron microscopy and photographic techniques have helped to provide new knowledge on the structure and formation of the cell wall; some excellent illustrations are provided in a comprehensive and detailed paper on this subject.

The complicated chemistry of the three main constituents of cell walls—cellulose, hemicellulose and lignin—is dealt with in Part 2. This is followed by Part 3, which contains five papers associated with the translocation of photosynthetic products to the cambium. Much of the recent knowledge on this subject has been brought about by newly developed carbon-14 techniques. One such series of experiments shows that there is a complex of processes involved in the translocation of organic material from the site of assimilation to the place of utilization, but that the physiological activity of the latter is probably the main factor in controlling translocation. The final part embraces some of the internal and external factors controlling wood formation, and it is emphasized more than once that more field experiments are required to elucidate the relationships which may exist between growth behaviour and environmental factors.

These papers will be welcomed by the various specialists in this complex subject, not only for their own worth and for points brought out in the associated discussions, but also for the lists of references. Editor and publisher have presented the material in a most commendable way.

C. J. Taylor

Green Medicine

The Search for Plants that Heal. By Margaret B. Kreig. Pp. 462 + 63 photographs. (Chicago and New York: Rand McNally and Company, 1964.) 5.95 dollars.

THE sub-title of this book, "The Search for Plants that Heal", roughly indicates its content. It is written in a popular and somewhat dramatic style by a professional American woman journalist with a scientific background —and also three young sons! The object of the book is to direct attention to the enormous amount of energy and money that is being applied in the United States, especially by the large drug firms, in attempting to produce new drugs from plants. Facts and figures quoted are likely to be an eye-opener for many readers, especially for those outside the United States. Some of the plants producing such well-known drugs as quinine and digitalis are also discussed.

There is much of interest in the book, such as the chapter on Mexican wild yams as sources of diosgenin, the chapter on *Rauwolfia* for reserpine and the remarks on the amazing narcotic plants of the Americas used for centuries by Amerindians. The writer gives reasons for the belief that in the next quarter of a century our knowledge of the drug plants of the world will increase greatly and that there will be much activity in their investigation.

F. N. Howes

Dissection of the Locust

By Dr. Joan G. Thomas. Pp. 72. (London: H. F. and G. Witherby Ltd., 1963.) 8*s*. 6*d*.

UNTIL about twenty years ago, the advanced school pupil and university undergraduate were almost always introduced to insect anatomy by dissecting the cockroach. This insect was readily available and so also were accounts of its anatomy and instructions for its dissection. However, improved standards of hygiene have made the cockroach more difficult to obtain, and the establishment of many laboratory cultures of the migratory locust in Britain has provided an alternative, and in some ways superior, species with which to teach insect anatomy. Until now, two obstacles have impeded the widespread adoption of the locust for this purpose: there has been no dissection manual, and supplies of the adult insects have not been available on a commercial scale. Dr. Thomas's book has removed the first of these, and the removal of the second will no doubt soon follow.

The book has been written for sixth forms in schools and for undergraduate students, and the author has struck a very suitable balance between the requirements of these two classes of reader. After introductory notes on the life history, and on rearing and preserving locusts, the book deals in successive sections with the external features and the dissection of all the principal systems. The text is written very clearly, with the practical instructions for dissection usefully marked off from the rest of the text by being printed in italics; accounts of microscopical structures are printed in smaller type. An appendix gives brief notes on the making of permanent preparations and suggests a number of simple investigations that can be made with living locusts.

The book is amply illustrated with clear, fully labelled diagrams, enabling the descriptions and instructions for dissection to be easily followed. It is well bound in a large sensible format, and can be recommended unreservedly to both students and teaching staff of the biological departments of schools and universities.

D. R. Ragge

The Two-nucleon Interaction

By Michael J. Moravcsik. (Oxford Library of the Physical Sciences.) Pp. viii + 154. (Oxford: Clarendon Press, 1963.) 18*s*.

The physics of the two-nucleon interaction has recently reached a breathing-space. Our empirical knowledge of the proton–proton interaction is now essentially complete throughout the elastic scattering region; a similar wealth of information on the neutron–proton interaction is much harder to win and will not all be available for several years. This review of the subject is therefore timely and welcome.

The book is divided into two equal parts. The first deals with the experimental information and with the simple theoretical apparatus (*S*-matrix, potential models, phase shifts) needed to describe it phenomenologically. The second half discusses the attempts that have been made to provide a fundamental theory of the nucleon–nucleon interaction (pion potentials, dispersion relations, exchange of pion resonances).

Within the restricted format of an Oxford Library volume it would of course be impossible to develop, for example, the theory of dispersion relations from scratch; nor would it be desirable in a monograph such as this. Enough is said, however, to indicate what sort of theories there are, their premises and their mathematical expression, the type of results to be obtained, and the difficulties involved. Together with the full experimental survey, this gives a good clear picture of our present state of knowledge of the interaction which lies at the heart of so much modern physics.

J. M. Soper

Intra-ocular Lenses and Implants

By Prof. Peter Choyce. Pp. x + 211. (London: H. K. Lewis and Co., Ltd., 1964.) 90*s*. net.

This is a beautifully produced book, well illustrated and liberally provided with coloured illustrations of a high calibre. The illustrations have the great merit of showing at a glance what they are intended to convey, and are self-explanatory to such an extent as to render the captions almost redundant. Prof. Choyce, a master equally in explaining basic principles and detailed operational techniques, surveys the brief history of lens prostheses and puts his weight firmly behind Strampelli's fixed-length acrylic anterior chamber implant. Various types of fixation are described and the special requirements of aniridic eyes carefully set out. If one wonders to what extent Gullstrand's schematic eye is truly representative of the optics of the non-existent average eye—witness only the dependence on age which is not negligible but which has heretofore been ignored in 'schemes'—one may, none the less, provisionally follow Prof. Choyce in the acceptance of his theoretical basis. It may be argued that, if the eye were not normal before the insertion of the implant, it would scarcely be so afterwards. His Tables 22 and 23 showing the residual spherical and cylindrical errors assuage one's fears and, at the same time, demonstrate the progressive improvements of the technique.

Implants can also be used in dealing with keratoplasty and for the restriction of vitreous prolapse into the anterior chamber, although the long-term effects following these, and other, operations remain to be established. Prof. Choyce believes that later editions of this monograph will be more helpful in throwing light on these questions. This leads to a feature of this book which he has done his best to prevent one from overlooking. In his commentary on Spinoza, Prof. Hampshire emphasizes the philosopher's severely analytical style, as typified by the exclusion of all adornment and personal traits: the writer's ego appears in his treatises no more than it does in Euclid's theorems. The very reverse is true of the monograph under discussion. If the reader is reminded of '57 Varieties' when reading references to "Choyce mark III, IV, V implants", he may well be pardoned for questioning the objectivity of this highly personalized account. Prof. Choyce's surgical skill may match that of his pen. He cannot quote his patients' opinions: we have to wait for those of his peers.

R. A. Weale

Radionuclide

Von D. Kurt Schmeiser. Zweite, völlig neu Bearbeitete und Erweiterte Auflage von Radioaktive Isotope. Pp. xii + 282. (Berlin: Springer-Verlag, 1963.) 59 D.M.

The book is primarily intended as a guide for biologists, doctors, chemists and other scientists who want to use radioactive nuclides for radiography or analysis. It is quite easy to understand, and the main emphasis is on practical applications. There are numerous literature references up to 1961 which permit a study in greater depth when this is desired.

In seven main sections the book deals with the basic principles of atomic structure and the production of radionuclides, the interaction of radiation with matter, radioactive decay, radiation detectors, source applications of radionuclides and radiation protection.

Three new items are added to the second edition: the determination of low-energy radiation (^{3}H, ^{14}C) with liquid scintillation counting, γ-spectrometry and low-level counting. The chapter on liquid scintillation counting gives on eight pages a survey about the techniques involved, the properties of some scintillators and solvents in use and the advantages and disadvantages of the method. Compared with its importance nowadays, the γ-spectrometry is discussed rather briefly (six pages). The chapter on low-level counting mainly centres on the techniques for reducing the background, including anti-coincidence shielding.

In greater detail are discussed the techniques of activation analysis (14 pages) and autoradiography (25 pages). A number of useful examples are described of the application of the various techniques in the fields of chemistry, biology and technology.

The book is well written and can be recommended as a useful tool to those familiar with the German language.

E. Glueckauf

VARRO AND THE SMALL BEASTS: A BIMILLENNIUM FOR MICROBIOLOGISTS

By Dr. D. F. CHEESMAN

Bedford College, University of London

TWO thousand years ago, probably in 36 B.C., the Roman polymath, Marcus Terentius Varro, published his treatise on agriculture and husbandry, known as the *De re rustica*. Varro's birth in 116 B.C. at Reate (now Rieti) in the Sabine country is well attested[1]. In the first chapter of the book, the author remarks that he must make haste with the writing: "since my eightieth year warns me to get my luggage together for my departure from this life"[2]. Pliny the Elder records that the *De re rustica* was published in Varro's eighty-first year[3]. The bimillennium may thus be placed without great error in 1965.

The book is the only surviving intact work of the man whom Quintilian regarded as the most erudite of all Romans. It is one of the very few technical hand-books which survive from classical times. Most significant of all, perhaps, is that the *De re rustica* contains the first mention in extant literature of invisible micro-organisms, with the statement that these may be agents of disease.

The treatise is in the form of a conversation between Roman gentlemen versed in the different aspects of farming. The most expert of them all, one Gnaeus Tremelius Scrofa, discusses the choice of the site for a farmhouse: "Care must be taken in swampy localities . . . since in such places there grow certain minute animals (*animalia quaedam minuta*) which cannot be followed by the eye and which are carried with the air into the body by way of the mouth and the nostrils, there giving rise to serious diseases"[4]. Scrofa later emphasizes that the house should be built in a high and well-ventilated place: "Being exposed to the Sun throughout the day, it is more healthy, since any small beasts (*bestiolae*) that are bred nearby and carried in either are blown away or quickly die from desiccation"[5].

Such doctrine, though novel, is quite reconcilable with the Hippocratic theory of disease. Varro himself successfully applied Hippocratic principles during an epidemic when he was with Pompey's army in Corfu[6]. His account of diseases in farm animals does not depart from orthodoxy[7]. It is thus of all the more interest to contrast the first passage cited with analogous passages by writers who came directly or indirectly under Varro's influence.

The architect Vitruvius, a younger contemporary, gives evidence that he read and admired Varro. He had probably at least considered Scrofa's remarks when he made his recommendation concerning the choice of high sites for public buildings: "The neighbourhood of a marsh is thus avoided. When the morning winds reach the town with the rising Sun and, combining with the marsh clouds, spray the bodies of the inhabitants with the venomous exhalations of the swamp animals, the place will become pestilential"[8].

Two generations later, Columella, another admirer of Varro, gives advice on the location of the farmhouse: "Nor should a marsh be close to the buildings . . . for in the heat it gives off an unwholesome stench and breeds animals armed with stings which fly upon us in dense swarms. It also gives off plagues of swimming and creeping creatures, poisoned by the mud and the decaying sludge, from which strange diseases are often contracted, the causes of which not even the doctors can understand"[9].

Finally, and in a similar context, Palladius, a fourth-century writer who owes much to Columella: "A marsh, however, should by all means be avoided . . . because of the pestilence or the hostile animals which it generates"[10].

Vitruvius persists, as indeed men persisted for another nineteen centuries, in a miasmatic theory of the ague; but so much concession is made to the marsh beasts that the miasma is said to originate in their breath. Columella, in his vivid picture of swamp life, comes fortuitously closer than Varro to identifying the vector of malaria; but his animals all remain visible. Palladius seems to find no causal relationship between the animals and the pestilence. It appears, at all events, that the invisible *bestiolae* were just too much to accept, however respected the mind which conceived them.

We have too little of Varro's writings to assess his competence as a natural philosopher. The *De re rustica* is full of common sense, all that might reasonably be expected of such a work. Superstition extends no farther than such deference to the established religion as would to-day be held respectable in a landowner. Here and there one encounters a passage startling in its insight. The following plea by Scrofa for the experimental method may well be without parallel in classical literature: "The earliest farmers established most techniques by trial; their successors, in the greater part, imitated them. We must do both: imitate and try by experiment to do some things differently, following not chance but some kind of reason"[11].

It is not difficult to suppose that the man who wrote this could have made the extrapolation from the very small insects which lodge, all too sensibly, in the body's orifices, to yet smaller organisms which, unperceived by the senses, pass unhindered into the body. This great imaginative feat appears to have made no impression whatsoever on biological or medical thought. It was not until the seventeenth century that the learned Jesuit, Athanasius Kircher, in his essay on the plague, suggested that the pestiferous atoms of Democritus and the Epicureans, which had inspired Fracastoro to elaborate his theory of the *contagium vivum*[12], were, in fact, living animals, worms so small that "you would call them atoms, unless they were made perceptible by the most exquisite of microscopes"[13].

Varro, who, as a believer in an "Efficient Cause"[14], was as monotheistic as any Jesuit, may himself have conceived the *bestiolae* as a counter to the atomic theory of disease. We shall perhaps never know, however, whether the concept derived originally from a Greek source. Further uncertainty comes from the fact that Gn. Tremelius Scrofa was not, as the learned editors of the Loeb edition of *De re rustica* assume, a fictitious character with a suitably funny name (*scrofa* = breeding sow), but a distinguished writer on agriculture to whom Pliny[15] and Columella[16] acknowledge their debt. Varro, as a good encyclopædist, may be attributing to his *dramatis personae* the opinions held by their prototypes.

Whatever the truth of these matters may be, Varro gives the earliest hint in surviving literature of a world of organisms too small for the eye to detect. It would be pleasant if, during the two-thousandth anniversary of the book, a few microbiologists were to drink to his memory.

A SINGLE-GENE MUTATION OF *Chlamydomonas reinhardii* AFFECTING MOTILITY: A GENETIC AND ELECTRON MICROSCOPE STUDY

By Sir JOHN RANDALL, F.R.S., Dr. J. R. WARR, J. M. HOPKINS and ANNE McVITTIE

Department of Biophysics and Medical Research Council Biophysics Research Unit,
University of London, King's College, 26-29 Drury Lane, London, W.C.2

IT is clear that recent progress in microbiology, molecular biology and biochemical genetics has brought us to a new frontier in the understanding of the organism and its organization: and we may now hope that within a reasonable period of time some at least of the principles of morphogenesis and differentiation will be disclosed. The analysis of these principles has been pursued for many years, chiefly in higher organisms[1,2]. Although recent investigations with micro-organisms now allow us to think of morphogenetic processes in terms of genes and macromolecules[3], there are many daunting problems facing those who would wish to apply these ideas to still more complex living systems. In higher plants and animals the distinction between somatic and reproductive tissue does, in fact, greatly hinder the direct experimental examination of the genetic control of differentiation in such organisms. Consequently, one valuable method of attack is to focus attention on some more limited objective, such as a distinctive and well-characterized organelle, the basic features of which seem to be of universal occurrence; or alternatively on phage, for example phage *T*4, in the head assembly of which 7 genes are already known to be implicated[4,25]. Many of the leading workers on the Protista[5,6] have emphasized and demonstrated that these organisms display important features of morphogenesis and differentiation. Externally in many genera there are cilia and flagella; and cortically their basal bodies, roots and other attachments. Some groups such as algae possess, in addition to flagella, another type of organelle of morphogenetic interest, namely, the chloroplast, which has also been the subject of genetic and fine-structure investigations[7,8].

We have chosen to examine the morphogenesis of cilia and flagella and their basal bodies, and this article presents an account of our first experiments. In due course it may be possible to express the morphogenesis of a flagellum in terms of its genetic determinants and to distinguish between processes of self-assembly[9,10] sequential (genetic) control and subsequent regulation. Our first concern, however, has been to establish an appropriate experimental system and explore its potentialities.

The main features of the fine structure of the mature cilium or flagellum are now well established[11], particularly in contrast to the comparatively meagre amount of information available on the development of these organelles. Recently, both Ehret and de Haller[12] and our own Laboratory[13] have given descriptive accounts of the sequence of development of basal bodies in terms of fine structure for *Paramecium* and *Stentor*, respectively, and Schuster has examined the transformation of *Amoeba grüberi* from amœboid to flagellate[14]. For various reasons these organisms are unsuitable for our present investigation. The alga *Chlamydomonas reinhardii*, a biflagellate member of the Chlorophyceae, has many of the attributes necessary for our purpose. The fine structure of the flagella of a related species, *Chlamydomonas moewusii*, has been examined by Gibbs, Lewin and Philpott[15]. Although the electron micrographs reproduced by these authors are somewhat lacking in detail, there seems to be no reason to suppose that flagellum structure in *Chlamydomonas* spp. differs markedly from that found in so many other organisms. *Chlamydomonas reinhardii* is also suitable for genetic investigations: it is normally a haploid organism, has a short life-cycle and is very convenient for tetrad analysis[16]. Non-chromosomal inheritance has been demonstrated in the species[17].

Mutants of *Chlamydomonas* spp. with impaired motility have been isolated previously, notably by Lewin[18], although no structural abnormalities of the flagella were detected when these were examined in the electron microscope[15]. We shall now describe results obtained from the examination of a mutant of *Chlamydomonas reinhardii* induced in the presence of proflavine.

(*A*) *Genetics*. Cultures of wild-type *C. reinhardii* were obtained from the Cambridge collection and originally from R. P. Levine's laboratory. Experimental cultures were maintained at 25° C at an intensity of illumination of 500 ft.-candles provided by tubular fluorescent lamps. The culture medium was based on Medium I described by Sager and Granick[19] in which ferric chloride was replaced by 0·01 g/l. ferric citrate and 0·1 g/l. citric acid.

Wild-type (mating type +) cells were grown for six days on solid medium containing 100 mg/l. proflavine hydrochloride. (Since no estimation of mutation rates in the absence and in the presence of proflavine has been made, the possibility of spontaneous mutation certainly can not be excluded.) Selection of non-motile, so-called paralysed, mutants from these cells was made in two stages:

(1) Non-motile cells sink in liquid culture and this provides a simple basis for a mutant-enrichment technique[20]. Therefore about 10^6 cells were transferred from the proflavine-containing plates to 100 ml. liquid medium in a separating funnel and afterwards incubated for a further three days. The vast majority of cells in such a culture are motile and are found close to the surface. In order to obtain an enrichment in the proportion of non-motile types, 1 ml. of the above culture was taken from the bottom of the funnel and used for the second stage of selection.

(2) This cell suspension was diluted and plated on semi-solid medium (containing 0·5 per cent 'Oxoid No. 3' agar) at a density of about 60 cells/dish. On this medium, non-motile mutants form rather small dark-green colonies in contrast to the large, paler colonies of wild type. One small colony was found to consist of cells with non-motile flagella of approximately normal length. The flagella of a few cells showed slight, unco-ordinated twitching which in no case resulted in any movement of the whole organism. Cells of this strain always sink to the bottom

in liquid cultures. The strain was re-isolated from a single colony and designated pro_1. This mutant strain was crossed to wild type and dissection of resulting tetrads carried out according to the method of Ebersold and Levine[21]. It was confirmed that gentle shaking favours mating of non-motile mutants[18]. The products of ten tetrads were cloned and classified for motility by two methods: by microscopic examination, and by their behaviour in liquid medium. In all cases, segregation for motility : non-motility was 2 : 2, which is in accord with a single gene control of the trait, although a chromosomal location for the gene has not yet been established.

(*B*) *Electron microscopy*. Examination of the fine structure of the flagella of the wild type of *Chlamydomonas reinhardii* and the mutant pro_1 was carried out in an RCA *EMU* 3*G* electron microscope using an accelerating voltage of 100 kV; the instrument was fitted with a 30μ objective aperture. Organisms in their normal liquid medium were fixed by draining the specimens of excess liquid and then adding a buffered solution of 1 per cent osmium tetroxide (*p*H 7·5) at room temperature for times varying from 5 to 50 min. Dehydration was achieved by passing the cells through a graded series of acetone solutions and then finally embedding in 'Araldite' in the usual way. Thin sections of the embedded cells were applied to copper grids coated with a carbon film and then double-stained as follows with the grids in an inverted position. The preparations were exposed to a saturated solution of uranyl acetate in equal parts of ethyl alcohol and water for 1 h at 37° C in a sealed chamber. The grids and sections were subsequently well rinsed in several changes of distilled water and the sections further stained by exposure to a solution of lead citrate for 35 min[22]. Preparations were then washed with a jet of 0·02 N sodium hydroxide and, afterwards, several times with distilled water.

The main features of the fine structure of cilia and flagella are well known, and the review already cited[11] discusses these in detail. Each flagellum consists (within a bounding membrane) of nine pairs of peripheral and apparently tubular fibres and a central pair. To one member of each of the outer nine pairs of fibres may be attached two short projections or arms. These extend in a circumferential direction towards the next fibre. Gibbons and Grimstone[23] consider that these arms all point in the same direction. The matrix of the flagellum, and particularly that region lying between the central and outer fibres, contains moderately densely staining components which have been interpreted in terms of subsidiary longitudinal fibres[23] and as radial lamellæ[24]. These finer details of flagellum structure, together with others recently observed in this laboratory, require further investigation and may be of importance in the wider concept of morphogenesis. In the present article we shall be concerned only with the main peripheral and axial fibres.

Fig. 1 shows a transverse section of a flagellum of *Chlamydomonas reinhardii*, wild type, in which the dispositions of the nine outer pairs and the central pair of fibres are clearly visible. In view of the appearance of flagella of the mutant now to be described it should be emphasized that the normal 'nine-plus-two' structure has been observed in all of many independent preparations of the wild type. Fig. 2 illustrates the appearance of the mutant (pro_1) flagellum in transverse section, and it is at once clear that the central pair of fibres is no longer present in its characteristic form, but has been replaced (in the section) by an irregular area of material of moderate density.

We have also examined the fine structure of the flagella of clones grown from the four members of a tetrad resulting from the cross between wild type and mutant. The structural abnormality observed in electron micrographs of flagella of the original mutant is also present in the clones grown from the two non-motile members of the tetrad. Conversely, clones grown from the two motile members have flagella of normal structure. Thus the gross phenotypic change to non-motility is correlated in the segregants with a significant change in fine structure.

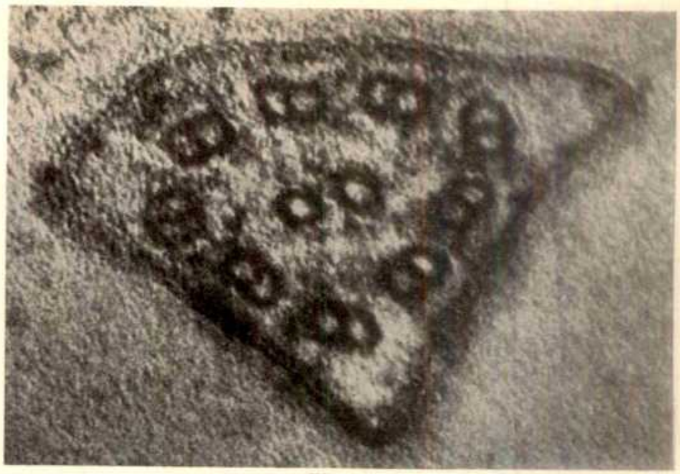

Fig. 1

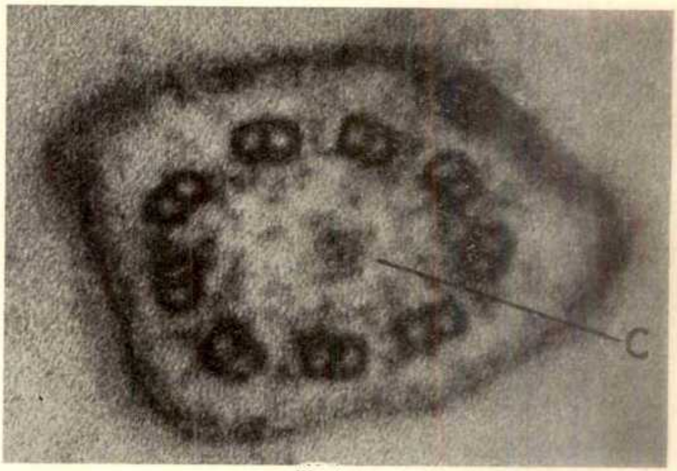

Fig. 2

Figs. 1 and 2. Electron micrographs of transverse sections of flagella of *Chlamydomonas reinhardii* (×225,000)

Fig. 1 shows the normal '9+2' fibre pattern observed in wild-type organisms; Fig. 2 illustrates the disorganized nature of the central pair of fibres in the mutant (as at *C*)

Discussion

It would be inappropriate to enter into detailed discussion of our results at this stage. Nevertheless a few comments can be usefully made. The association of non-motility and structural defect in a single gene trait is of direct and immediate interest. In the longer term sense it leads us to hope that other similar effects may be discovered which will lead to a better understanding of a specific morphogenetic process.

Examination of electron micrographs of the flagella of the mutant suggests that part, if not all, of the material of the axial fibres is still present and that it may sometimes appear in the form of small fibrils. Thus if protein units or even fibrils have been synthesized—and this is the obvious inference—their subsequent organization into the characteristic twin axial fibres of the normal flagellum has failed to take place. It is not yet known if the chemical nature of the axial material in the mutant is identical with that of the wild type. Clearly, the inability of the mutant flagellum to organize its chemical components in characteristic form could arise from differences in primary, secondary or tertiary protein structure. Further speculation along these lines is undesirable until it can be fortified by a more detailed knowledge of the chemical nature of the flagellum fibres.

Other possible differences between the fine structure of the flagella of wild type and those of the mutant are now being investigated. There are indications that the radius of the cylinder on which lie the nine outer pairs of fibres is larger for the mutant than for the control, but more measurements are required to justify this observation on statistical grounds. There appear also to be differences in the proportions of the complex basal body structure; these too require further examination.

Summary

(1) A mutant non-motile or 'paralysed' strain of *Chlamydomonas reinhardii* has been produced in the presence of proflavine and isolated.

(2) Electron microscope examination of the flagella of the mutant shows an abnormal structure, the most obvious feature of which is the apparent lack of a central pair of fibres in an organized form.

(3) Tetrad analysis of crosses between mutant and wild type has demonstrated a 1 : 1 segregation on the basis of motility and also in terms of fine structure (as described in (2)) in the electron microscope.

(4) *Chlamydomonas reinhardii* appears to be a suitable organism for the investigation of the morphogenesis of flagella. The mutant pro_1 of *Chlamydomonas reinhardii* is believed to be one of the first to be isolated with a clearly observable alteration in the fine structure of a well-characterized organelle, the flagellum.

We thank P. J. Hastings of the Botany School, University of Cambridge, for initiating us into various techniques of handling *Chlamydomonas*, particularly tetrad analysis.

ELECTROMAGNETIC WAVES FROM VERY DENSE STARS

By Prof. F. HOYLE, F.R.S., Dr. J. V. NARLIKAR and Prof. J. A. WHEELER
Department of Applied Mathematics and Theoretical Physics,
University of Cambridge

THE recent detection of X-rays from the region of the Crab Nebula and from a discrete source in Scorpius by Giacconi *et al.* and by Bower *et al.*[1–3] has much increased the interest in neutron stars (cf. Chiu[4] and Morton[5]). It has been considered important for the maximum mass of a stable neutron star to exceed that permitted for a white dwarf, about $1{\cdot}3\ M_\odot$. The original discussion of the problem by Oppenheimer and Volkoff[6], treating neutrons as a simple Fermi gas, gave a maximum mass of only $0{\cdot}7\ M_\odot$. However, allowance for a hard core nucleon potential increases the maximum mass and it is likely that in the stiffest possible situation with the pressure equal to the energy density the maximum mass for a neutron star does exceed that for a white dwarf[7]. This has been considered essential in order that neutron stars be formed during the course of stellar evolution.

We begin by pointing out that for actual stars possessing rotation the usual treatment of the maximum mass has no general validity. When gravity is balanced by centrifugal force in directions perpendicular to the axis of rotation there is no limit to the mass which may be supported in a disk-like structure. For a disk of radius a, thickness b, in which the material has angular momentum h per unit mass, we have the following relations:

$$h^2 a^{-4} = \omega^2 \simeq 2\pi G\rho \qquad (1)$$

$$P \approx 2\pi G b\rho . b\rho \qquad (2)$$

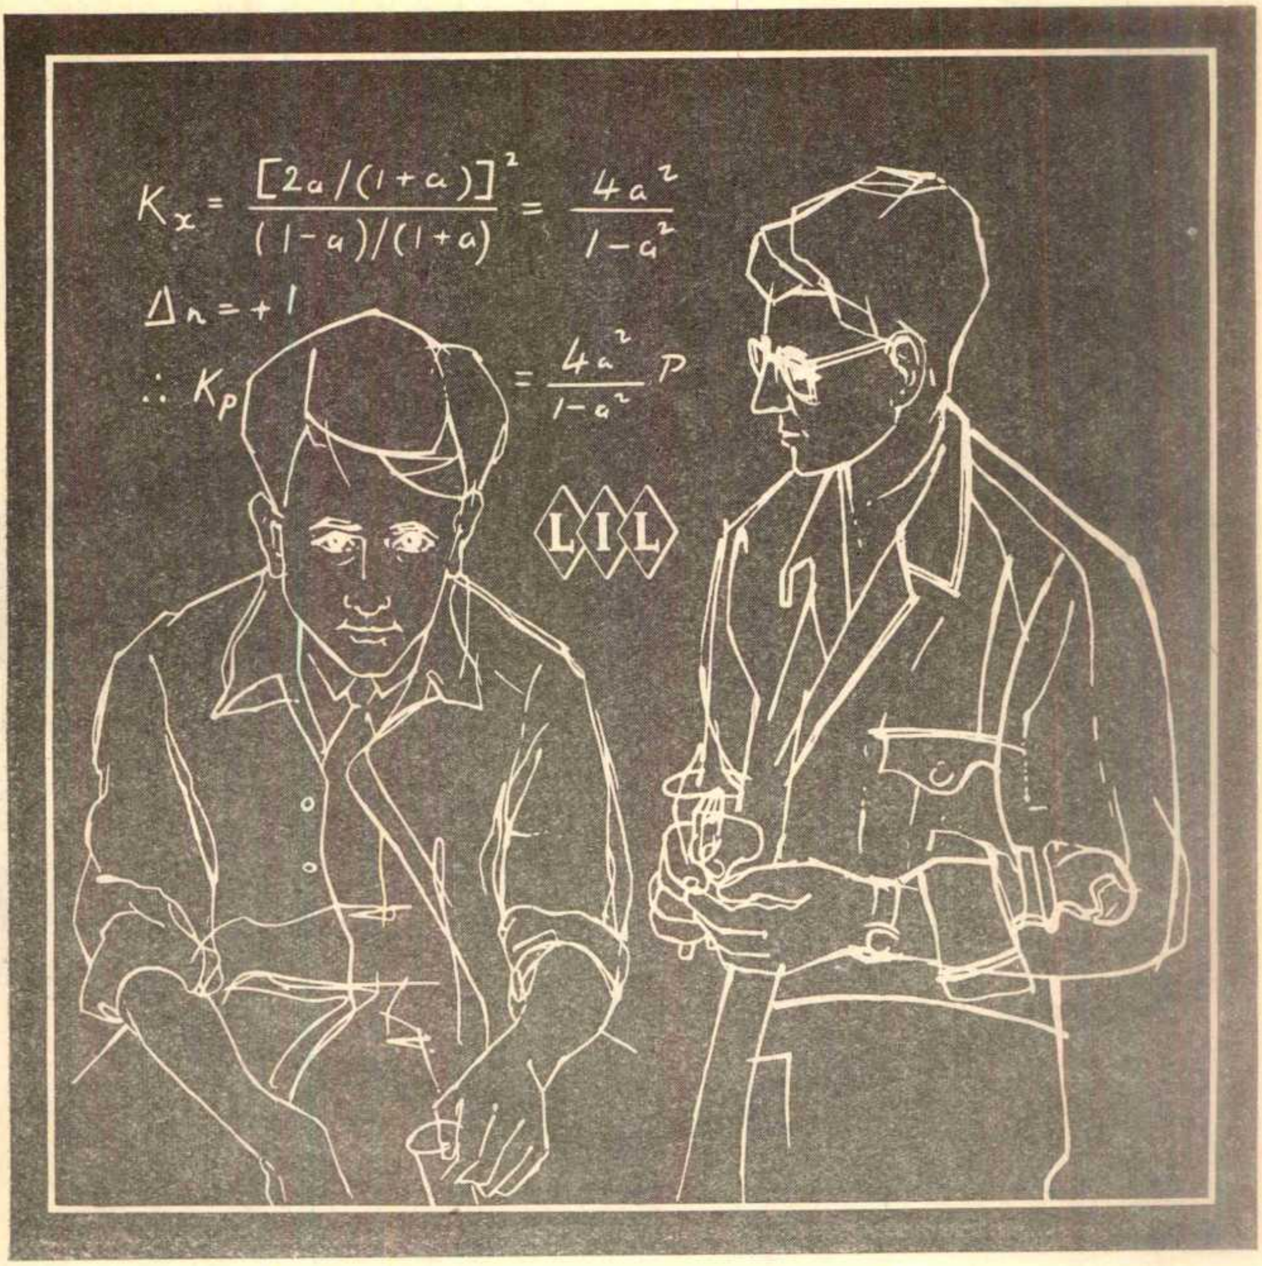
where P is the pressure. Equation (1) is necessary for the rotational support and equation (2) is necessary in order that the pressure shall balance gravity in the direction perpendicular to the disk. The mass M is given by:

$$M = \pi a^2 . b\rho \simeq \tfrac{1}{2} h \sqrt{\frac{P}{G^3 \rho}} \qquad (3)$$

in which a has been eliminated with the aid of equation (1) and b with the aid of equation (2). Whatever the dependence of the pressure on ρ, it is clear that M can be made as large as we please simply by increasing h. At constant ρ, b remains constant while a increases with h, so that b/a decreases with the increasing h and the disk-like property assumed here is enhanced as $h \to \infty$.

Our second point is that a neutron star is thought to be formed catastrophically, probably through the free fall collapse of a supernova. This means that such a star does not arrive gently at its stable configuration. Large dynamical velocities are developed and there must be oscillations about the stable configuration. For situations in which the dimensions of the equilibrium structure are not much greater than the critical Schwarzschild radius, the dynamical speeds are not much less than speed of light. Since for neutron stars the dimensions of the equilibrium structure are taken as not more than 3–10 times the Schwarzschild radius, the corresponding speeds are $\sim c/3$, and the associated dynamical energy is of order 10^{20} ergs gm^{-1}. Not until after this energy of oscillation has been dissipated can the stable structure be arrived at. The question we wish to raise is: How is the dynamical energy of oscillation, totalling $\sim 10^{54}$ ergs for a star of mass $5\ M_\odot$, dissipated? Our suggestion is through the emission of electromagnetic waves.

For definiteness we shall consider a neutron star with a mean internal density of order 10^{15} gm cm^{-3} and with dimensions $\sim 10^6$ cm. It seems unlikely that the magnetic intensity at the surface can be much less than 10^{10} gauss. Even a star with such a small dipole field as the Sun, 1 gauss at a mean density of ~ 2 gm cm^{-3}, would develop a polar field of $\sim 10^{10}$ gauss if it were catastrophically contracted to $\sim 10^{15}$ gm cm^{-3}. (The magnetic field would not be squeezed out of the star. Although neutrons dominate, electrons and protons are



$K_x = \frac{[2a/(1+a)]^2}{(1-a)/(1+a)} = \frac{4a^2}{1-a^2}$
$\Delta n = +1$
$\therefore K_p = \frac{4a^2}{1-a^2} P$
LIL

LAPORTE BLUEPRINT FOR RECRUITMENT AND EMPLOYMENT

Great importance is given by the Laporte Group to the recruitment of staff, particularly in the technical field; and increasing responsibility for the successful execution of its processes results from the knowledge and skills of Laporte personnel. The Group has developed its own training methods in order adequately to equip newcomers to play their part in the overall operations of their Company. Particular attention is also given to progressive modern methods of personnel development, aimed at providing satisfactory and rewarding employment for people of ability.

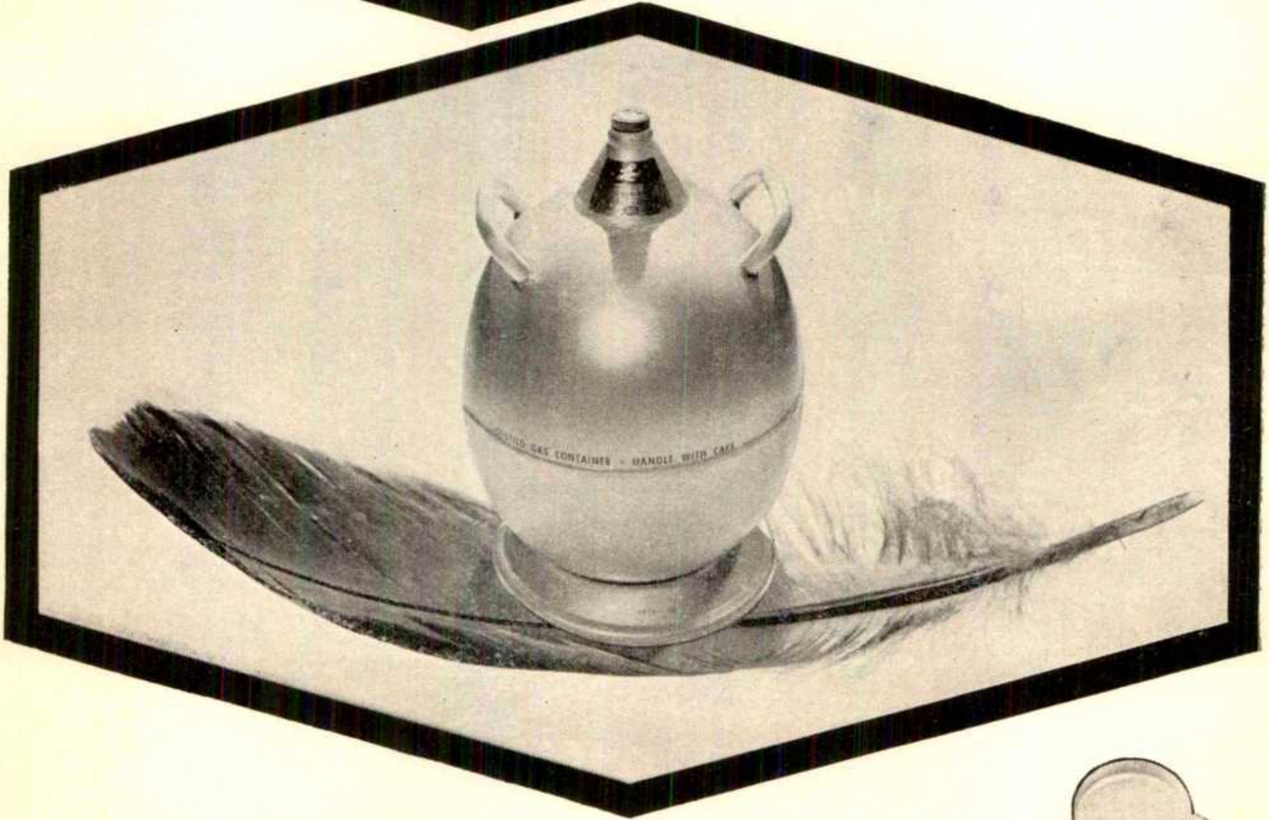
UNION CARBIDE



Since cryogenic techniques are being widely employed in both pure and applied research, most laboratories now require supplies of liquid gases. To meet this need, Union Carbide has developed special liquid gas containers combining high thermal efficiency with portability. Specifically intended for laboratory use, the Union Carbide LD 10 and LD 25 liquefied gas containers are constructed entirely in welded aluminium which means that they are many times lighter than conventional copper dewars, and therefore easier to handle, particularly when full.

Both units incorporate Union Carbide's 'SuperInsulation' which results in holding times often more than twice as long as those of ordinary containers. The design is such that evaporation losses will not exceed 3% per day in the case of oxygen and argon, and 4% per day in the case of nitrogen. This means that gas storage costs amount to only half of those incurred when standard storage equipment is used. Filling and pouring are safe, easy and efficient. With the LD 25 container, which weighs 16 lb. empty and has a capacity of 25 litres, the entire contents can be poured in less than 90 seconds. The performance of the LD 10, which weighs 10 lb. empty and holds 10 litres, is comparable. Please write for further details.

WCWISE

also present, the sum of the top of their Fermi distributions being equal to that of the neutrons. The electrons have high conductivity.)

Dynamical oscillations of the main body of a neutron star evidently imply an oscillation of the associated magnetic field. The oscillations will be of a hydromagnetic character so long as the hydromagnetic wave speed $H\sqrt{4\pi\rho}$ is appreciably less than c, as it is in the interior of the star. But ρ falls steeply at the surface, the scale height being only a few centimetres. Evidently, for $\rho \simeq 1$ gm cm^{-3} we have $H/\sqrt{4\pi\rho} \sim c$ and the situation becomes electromagnetic rather than hydromagnetic, with the displacement current of crucial importance. Outside the immediate surface we expect electromagnetic waves to be generated, $\lambda/2\pi$ being of the order of the dimensions of the star. This follows because the frequency ν is $v/2\pi R$, where v is the dynamical speed of oscillation, $\sim 10^{10}$ cm sec^{-1}, and R is a characteristic dimension. Hence, $2\pi\nu \simeq 10^4$ c/s, and $\lambda/2\pi \simeq 3 \times 10^6$ cm. The simplest example is that in which an oscillating star with an initial non-uniformity of rotation produces oscillating variations in the winding of a toroidal magnetic field, requiring an oscillating component in the axial current, that is, a Hertzian oscillator. The emission of electromagnetic waves serves in this case to damp the initial non-uniformity of rotation. On the other hand, an oscillating component in the toroidal current would seem to be necessary in order to damp out the radial oscillations of the star.

The possible rate of emission of energy by electromagnetic waves is very large. The Poynting vector $c\mathbf{E} \times \mathbf{H}/4\pi$ has magnitude $cH^2/4\pi$, which gives $\sim 3 \times 10^{29}$ ergs cm^{-2} sec^{-1} for $H = 10^{10}$ gauss. The total surface area is $\sim 10^{13}$ cm^2, so that the total emission rate might be as high as 3×10^{42} ergs sec^{-1}, although a lower value, say 10^{41} ergs sec^{-1}, would be a more conservative estimate, since the oscillating component of the field is likely to be less than the total field. However, even 10^{41} ergs sec^{-1} is sufficient to dissipate the available store of $\sim 10^{54}$ ergs in $\sim 10^{13}$ sec $= 3 \times 10^5$ years.

It is important that no propagation difficulty arises. Electromagnetic waves are damped out in a few wave-lengths when the dielectric constant:

$$1 - \frac{Ne^2}{\pi m \nu^2} \qquad (4)$$

becomes negative. Here N is the electron density and e,m are the electron charge and mass. Putting $2\pi\nu = 10^4$ c/s, it is easily seen that (4) is zero for $N \simeq 3 \times 10^{-2}$ electrons cm^{-3}. While this is only very small compared with the internal density of a neutron star, it is much greater than the likely exterior density at a few radii out from the surface, simply because the radius exceeds the scale height by a large factor $\sim 10^6$. The point is that the strong gravitational field of the star creates a near-vacuum immediately outside itself, and the electromagnetic waves are free to travel out into space. Moreover, any residual gas outside the star would simply be swept away by the pressure of the electromagnetic waves.

How does the electromagnetic flux from an oscillating neutron star lead to observable effects? So long as the dielectric constant (4) is positive the waves pass essentially freely through space, but a critical condition arises if (4) becomes negative, that is, if N exceeds $\sim 3 \times 10^{-2}$ electrons cm^{-3}. The waves will be reflected from any cloud they encounter in which this condition is satisfied, and the cloud is then subjected to radiation pressure. The consequent compression increases N so that the pressure, once started, continues. Although radiation pressure is usually thought of as a weak effect—this is true for optical radiation—the electromagnetic flux from a neutron star can be so large that dramatic possibilities arise.

Consider the case of the Crab Nebula. The total mass of the gaseous filaments is about $0{\cdot}1\ M_\odot$, which is about the mass of interstellar gas to be expected in a volume of 1 pc^3, the volume of the Crab. The filaments are in outward motion with speed $\sim 1{,}000$ km sec^{-1}, so that the total outward momentum of the gas is $\sim 2 \times 10^{40}$ gm cm sec^{-1}. If this momentum has been derived from radiation, the energy of the radiation must have been 2×10^{40} c. Taken over 1,000 years the necessary mean energy output is $\sim 2 \times 10^{40}$ ergs sec^{-1}, close to the value 10^{41} ergs sec^{-1} estimated here. Hence it is possible that the observed outward momentum of the Crab has been derived from the electromagnetic flux.

Using 10^{41} ergs sec^{-1} for the total flux, the flux per unit area at $\sim 10^{17}$ cm from the emitting star is $\sim 10^6$ ergs cm^{-2} sec^{-1}. Reflected normally from a surface this flux exerts a pressure of $\sim 10^{-4}$ dyne cm^{-2}. Since reflexion occurs in only a few wave-lengths, in $\sim 10^8$ cm, the reflecting zone can indeed be thought of as a very thin layer in which the internal pressure must build up to match that due to the reflexion, $\sim 10^{-4}$ dyne cm^{-2}. If the electron density is 3×10^{-2} cm^{-3}, a mean electron energy of 10^{-2} erg $\simeq$ 10 BeV is necessary to supply this pressure. Although this estimate would not be correct if the electron density were to increase to much more than 3×10^{-2} cm^{-3} in a distance of $\sim 10^8$ cm, it is clear that any steep increase of density must imply violent non-uniformity in the thin-surface zone, and that particle acceleration could well take place in the ensuing fine scale motions. The critical behaviour of the refractive index would therefore appear to provide a mechanism for the generation of the high-energy electrons necessary to explain the synchrotron emission of the Crab. If the electrons were derived from the star itself it would be hard to understand why their energies were not immediately degraded through synchrotron emission in the very high magnetic fields close in by the star.

Turn back to the formation by collapse of a neutron star: why should this phenomenon show up as a supernova? Hoyle and Fowler[8] considered that, while the inner regions of a supernova collapse, the outer regions are thrown explosively off into space through a rapid release of nuclear energy, but these considerations apply only to supernovæ of Type II. For Type I supernovæ there may well be no explosive emission of an outer shell. There is the possibility that the optical radiation of Type I supernovæ comes from circumstellar clouds, distant perhaps as far as 10^{16} cm, that are activated by the ensuing electromagnetic flux.

We end by enquiring whether a similar process might occur on a still larger scale. Ginzburg[9] has considered the problem of the magnetic fields associated with massive objects, 10^6–$10^8\ M_\odot$. The problem appears essentially different, however, so long as one is dealing with a single coherent object. The wave-length would in any case be much larger, $\sim 10^{13}$ cm, and there would be a propagation difficulty similar to that aforementioned for ordinary stars. On the other hand, there is the possibility[10] that rotation may cause a massive object to break up into a swarm of neutron stars and/or white dwarfs. In such a situation each neutron star would behave essentially independently of the others, and with $\sim 10^7$ such stars the intensity of the phenomenon would be multiplied by this factor. The total energy available for electromagnetic radiation would then be $\sim 10^{61}$ ergs. A process of high efficiency, converting this energy into cosmic-ray electrons, would be necessary if the strong radio sources were to be explicable in these terms.

It is of considerable interest that the momentum associated with this total energy efflux is $\sim 3 \times 10^{50}$ gm cm sec^{-1}, which is sufficient to endow 10^{43}gm ($5 \times 10^9\ M_\odot$) with a recoil speed of 300 km sec^{-1}. The possibility must therefore be considered that a marked disturbance in the whole of the interstellar gas within a galaxy could be produced. Indeed, the possibility must not be excluded that the interstellar gas might be entirely expelled from a galaxy, or—if the gas were a sufficiently large fraction of the total mass—that a whole galaxy might be disrupted and scattered.

OBITUARIES

Prof. James Franck, For.Mem.R.S.

PROF. JAMES FRANCK died on May 21 at the age of eighty-one years. Born in Hamburg on August 26, 1882, Franck went to school there with indifferent success—as he was fond of relating—because he had trouble with classic languages. He began to study chemistry and geology in Heidelberg, but soon turned to physics and moved to Berlin where he graduated as Dr.Phil. in 1906, with a paper on ion mobility in gases. In 1907 he became research assistant to Prof. H. Rubens, in whose colloquia I first met him in 1908. I had the great good fortune to win his friendship and that of his family and to retain it for nearly sixty years. Only recently I was able to spend some weeks with Franck, visiting old friends together all over Europe, until a few days before his sudden death in Göttingen, on May 21.

In the First World War Franck went out as a private, was wounded, decorated and returned as a lieutenant. He was then assigned to a group led by the chemist F. Haber, who later, in 1918, made him a division head at the Kaiser-Wilhelm Institute for Physical Chemistry in Berlin-Dahlem.

How well I remember his famous lecture on May 22, 1914, "On the Excitation of the Mercury Resonance Line 2536 Å by Electron Impact" in which he reported his joint work with Gustav Hertz, which gave strong support to Bohr's new theory of the atom. Einstein said to me: "It's so lovely, it makes you cry!" Many a discussion between Franck and Otto Stern about those experiments I have listened to during the War years, whenever Franck happened to be in Berlin.

In 1920 Franck was called to a chair in Göttingen. Haber's farewell speech—at a party which Otto Hahn and I arranged—ended with the words: "There are three stages in the life of a scientist: becoming, being and representing; may representing come easy to you". I think Franck did not enter that last stage until a few months before his death, and it was not easy for him, despite the many honours that have come his way, among them the Nobel Prize in Physics in 1926 jointly with Hertz, the Max Planck Medal in 1953, the Rumford Medal in 1955, membership in many learned societies, and the election, in March 1964, as Foreign Member of the Royal Society.

Göttingen saw Franck's happiest and most fruitful period; he remained attached to it, received its honorary citizenship in 1953, and it is an odd turn of fate that he died there. There he did all his work on the transfer of energy in molecular collisions, as in the processes called quenching and sensitized fluorescence. Franck discovered the method of determining the heat of dissociation of diatomic molecules from band spectra by extrapolating the vibrational levels. His discussion of the coupling between electron transitions and vibrational motion led him to formulate the principle which was later put in wave-mechanical form by Condon and is known as the Franck–Condon principle. Thus the intensity distribution in band spectra and the existence of continuous molecular spectra came to be understood. The influence of those ideas has been far-reaching, particularly in photochemistry. His many pupils, still attached to Franck in affection and devotion, include such famous names as Blackett, Condon, Kopfermann, Kroebel, Maier-Leibnitz, Oppenheimer and Rabinowitch, to mention some of them.

Those happy days ended when Hitler came to power. When the racial laws were announced, Franck published a courageous open letter in which he resigned his chair. In view of his distinguished war service he might have been allowed to stay, but he did not wish to serve under a Government which treated his fellow Jews as outcasts. After an interlude at Copenhagen, with Niels Bohr, he went to the United States, first to the Johns Hopkins University and then to the University of Chicago, as professor of chemistry. Here his efforts were devoted to the elucidation of the most important of all photochemical reactions, the photosynthesis performed by green plants. It is a borderline problem between physics, chemistry and biology, and one of appalling complexity. Franck's last paper on that subject, in collaboration with J. L. Rosenberg, went to press only a few weeks before he died.

During the War he interrupted his own work for two years to direct the Chemistry Division of the Metallurgical Laboratory of the University of Chicago, a part of the Manhattan Project. He saw it as his duty to help develop a nuclear weapon as long as Hitler might be doing the same. But he felt strongly that the United States should not be first in using it, and other scientists felt similarly. Two months before Hiroshima, a joint letter which became known as the "Franck Report" was sent to the U.S. Secretary of War, Henry L. Stimson, presenting strong and wise arguments against the unannounced use of that dreadful new weapon and suggesting that its power be demonstrated by publicly exploding it over an uninhabited area. Perhaps the nuclear arms race could have been avoided if that letter had been heeded.

Franck enjoyed talking about his problems, not so much to explain them to others as to clarify his own mind. Once a problem had aroused his interest he was completely captivated, indeed obsessed by it. Common sense and straight logic were his main tools, together with simple, mostly home-made apparatus. His research followed an almost straight line, from his early studies of ion mobilities to his last work on photosynthesis; it was always the energy exchange between atoms or molecules that fascinated him.

Franck was equally interested in people. His kindness and generosity, not only to his friends and family but to everybody who needed help, were known to all who knew him. He was the most lovable of men because he loved people; kindness shone from his eyes. There must be many beside myself who now feel they have lost one of their best friends.

I wish to thank O. R. Frisch and H. G. Kuhn for valuable help in writing this notice. LISE MEITNER

Prof. Isadore Fankuchen

THE death of Prof. I. Fankuchen on June 27 at the age of fifty-nine leaves a great gap among crystallographers in the United States and particularly, also, in Britain. He was a figure very well known and loved in both countries.

His life shows him as a man devoted to research and teaching in his chosen field of crystallography. Educated at the Cooper Union, he passed on to Cornell University and thence to various other appointments in the United States. He came to England to work with Sir Lawrence Bragg at Manchester in 1934. He had already started his interest in crystallography, although fundamentally he was a physicist, and it was the physical interest rather than the chemical or biological that inspired his work. He found that in X-ray investigations he was able to apply the physics in more and more refined ways to problems of interest in industry and biology.

From Manchester, he joined me in Cambridge at the very exciting time, in 1936, when the first protein crystals were being examined by X-rays. His point of entry was the examination of the sterols which, in the form of vitamin D and its analogues, has just come into biological and pharmacological interest. His earliest work was on the structure of the uranyl compounds and he might well have gone on with this, for he was able to detect by the somewhat primitive methods of the time the presence and structure of the uranyl complex, UO_2, as an independent element in the uranium salts. Here he co-operated with Dr. Dorothy Crowfoot and me in an extensive investigation reported in the chemistry of the steroids (*Phil. Trans. Roy. Soc.*, A, 239, 135; 1940).

However, very soon after he arrived at the Cambridge laboratory his interest was diverted to the first examination of tobacco mosaic virus solutions, prepared by Bawden and Pirie. These turned out to be something quite different from anything that had been examined before; they are composed of long particles with a strong tendency to parallel packing which we now know is typical of the rod-shaped viruses. Before the development of the electron microscope this all had to be worked out by X-ray and optical methods.

Fankuchen threw himself into this examination. He excelled in the devising of apparatus specially tailored for the purpose. One problem was that of examining the liquid crystals at very low angles, and for this monochromatic X-rays were essential. He devised an X-ray monochromator made of a pentaerythritol crystal sliced in such a way that it could give a very narrow beam of strictly monochromatic radiation of high intensity. With this he investigated the variation of the photographs for tobacco mosaic virus solutions where the mutual distance between the rod-like particles was a function of the ionic strength, the *p*H and the dilution of the solutions. This examination dealt, not so much with the virus itself, but with the long-range forces between virus-like particles and, indeed, any kind of colloidal particles in solution. His work here was finally recorded some years later in the X-ray and crystallographic studies of plant virus preparations (*J. Gen. Physiol.*, 25, 111; 1941).

In 1938, Fankuchen left Cambridge and came to Birkbeck College, London, where I had just become professor of physics, and continued his virus investigations. The War intervened and he returned to the United States where he was later appointed professor of physics in the Polytechnic Institute of Brooklyn, a post which he held until his death.

During the War he took an active part in the investigations concerned with the use of snow and ice for military tactics, particularly in the project for airborne snow vehicles (weasels) and for the necessary studies to set up the *Habakkuk* ice ship which was conceived but never built on the full scale.

It was at Brooklyn Polytechnic, an extremely democratic, lively organization, that "Fan" (as he was known to all) found his true vocation as a teacher and director of research. The great growth of the use of X-ray analytic methods in the United States, particularly in industry, is to a very large measure due to his inspiration. He was able to imbue generations of students with the same devotion to the subject he himself had. This was not only in the Polytechnic itself, but also at Woods Hole in what he called his "Summer Clinics", where every year he taught a set of volunteers from industry in a fortnight all they needed to know of X-ray method. Fankuchen thus played a large part in spreading the ideas of crystallography and the benefits of crystallography to American industry, where it is more securely based than it is in Britain.

He was also extremely active in promoting the organization of crystallography in the United States and internationally, being one of the founders and, ultimately, the president of the American Crystallographic Association. He became the chairman of the National Research Council Committee on X-ray Crystallography.

Not only was he a devoted teacher, but he was a strongly critical supervisor; no shoddy work was to be tolerated. He further demonstrated this in his work as an editor of the *Acta Crystallographica*, the international crystallographic journal. Fankuchen helped greatly to strengthen and perpetuate the links between British and American crystallography. He was one of the effective founders of the International Union of Crystallography in 1945.

He will be remembered not so much for his scientific achievements as for his personality and inspiration. His ebullient good humour, friendliness and helpfulness, and his zest for life, made him one of the best-loved figures in American science.

Fankuchen died as he had lived. Stricken by cancer in 1962, he continued, in spite of two operations, all his lecturing work at Brooklyn and carried out his "Summer Clinic". He gave the last three-hour lecture at this Clinic on June 24 and then collapsed. He was taken to hospital and died only three days later, a life well spent. He leaves behind a wife and son.

J. D. BERNAL

NEWS and VIEWS

Physical Chemistry in the University of Oxford: Prof. R. E. Richards, F.R.S.

ON October 1, Dr. R. E. Richards will succeed Sir Cyril Hinshelwood as Dr. Lee's professor of chemistry at Oxford (see p. 958 of this issue of *Nature*). Since 1947 he has been a Fellow and Tutor of Lincoln College, in which capacity he followed the late N. V. Sidgwick. Since 1948 he has worked, first as a University demonstrator and later as reader, in the Department over which, in its recently somewhat reorganized form, he will preside. Dr. Richards was educated at Colyton Grammar School, Devon. He was an Exhibitioner of St. John's and later Senior Demy of Magdalen College. In 1954 he was awarded the Corday–Morgan Medal of the Chemical Society and in 1955 he was a Research Fellow at Harvard. He was elected to the Royal Society in 1959. His first research work was in the field of infra-red spectroscopy, but for the past fifteen years or so he has worked mainly on magnetic phenomena. It soon became evident that measurements of nuclear magnetic resonance were capable of throwing a great deal of light on very varied chemical problems, and Dr. Richards has been one of the foremost leaders in its development and application, winning thereby world-wide recognition. Dr. Richards takes over the Department at a moment of considerable expansion of its already vigorous activity, and it is fortunate to be passing into the charge of one with such eminent qualities.

The Torry Research Station: Dr. G. A. Reay, C.B.E.

Dr. G. A. Reay, who retires from the directorship of the Torry Research Station, Aberdeen, in October, was born on May 31, 1901, in Aberdeen. From Robert Gordon's College he went to the University of Aberdeen, obtaining his M.A. degree in 1921 and his B.Sc. in 1923, winning a senior Kilgour scholarship with which he commenced research in biochemistry. After a further year at Aberdeen he moved to Emmanuel College, Cambridge, and continued his research under the late Sir Frederick Gowland Hopkins. He was awarded a Carnegie research fellowship in 1926 and in 1927 obtained his Ph.D. In September 1927 Reay joined the staff of the Department of Scientific and Industrial Research Food Investigation Organization, becoming one of a small team of enthusiasts who set out to investigate and improve the handling of fish at sea. The Torry Research Station was not yet in existence, but Reay and his colleagues successfully demonstrated the value of adequate washing and proper icing procedures, and also the benefits of freezing fish at sea. The Torry Research Station was opened in October 1929, Reay being one of its first scientists and concentrating on the mechanism of protein denaturation in frozen fish. He soon began stressing the greater importance of low storage temperatures than of rapid freezing, a view at variance with much contemporary thinking. On the retirement in 1937 of the Station's first Superintendent, Mr. A. L. Lumley, Reay was appointed officer-in-charge, becoming superintendent in 1947 and director in 1958. He was elected a Fellow of the Royal Society of Edinburgh in 1955, and was awarded an O.B.E. in 1949 and a C.B.E. in 1958. Dr. Reay is an able musician and a keen angler.

Dr. J. A. Lovern, O.B.E.

Dr. J. A. Lovern, who has been appointed to succeed Dr. G. A. Reay as director of Torry Research Station as from November 2, was born in Liverpool in 1906. Dr. Lovern gained a first-class honours B.Sc. degree in chemistry at the University of Liverpool in 1927 and a Ph.D. in 1929 for investigations of the chemistry of fish oils under Prof. T. P. Hilditch. Thus began his professional acquaintance with fish, and also with Aberdeen, for he had to prepare his oil samples on board the research vessel of the old Fishery Board for Scotland. Joining the staff of the Torry in April 1930, when the Station was but six months old, Dr. Lovern gained international fame before the Second World War for his outstanding and varied chemical and biochemical investigations of fish oils. The University of Liverpool recognized this achievement by awarding him a D.Sc. in 1937. Two and a half war years in Washington, D.C., with the British Food Mission allowed Dr. Lovern to become thoroughly acquainted with the United States and Canadian fish industries and related research. Returning to Torry in 1945, Dr. Lovern enhanced his academic reputation by his notable work on the more complex lipids and the lipoproteins of fish, being promoted senior principal scientific officer on special merit in 1947. At the same time he became responsible for the Station's by-products research, especially on fish meal, and as a result he has become increasingly engaged in advisory work and sponsored research for the Association of Fish Meal Manufacturers and, since 1959, for the International Association of Fish Meal Manufacturers, of the Scientific Committee of which he has been chairman since its inception. Dr. Lovern was elected a Fellow of the Royal Society of Edinburgh in 1960 and received an O.B.E. in 1962. His hobbies include hill walking, natural history and alpine plant culture.

Royal Greenwich Observatory: Dr. O. J. Eggen

Dr. O. J. Eggen, formerly of the Lick Observatory, California, has joined the staff of the Royal Greenwich Observatory at Herstmonceux (Sussex). An authority on photoelectric photometry, he has put forward views on moving groups of stars considered most significant in relation to the history of the galaxy. He worked for five years at Herstmonceux before returning to the United States, where for three years he has been a professor in the California Institute of Technology and had use of the 200-in. telescope on Mount Palomar. Dr. Eggen will work as a temporary senior principal scientific officer at the Royal Greenwich Observatory.

Government Expenditure on Science

In reply to various questions in the House of Commons on July 2, total expenditure in the United Kingdom on all branches of oceanography and marine biology in 1964–65 was estimated by Sir Edward Boyle at about £2·17 million; Government expenditure on medical research in 1963–64 at £18·5 million, of which £7 million was for the Medical Research Council. Expenditure by the Department of Scientific and Industrial Research on seven basic research projects in scientific documentation at universities and colleges was estimated at £100,000, excluding research at the National Physical Laboratory. The new grant arrangements with the Association of Special Libraries and Information Bureaux would allow for an expenditure of up to £20,000 a year for a research programme in this field.

Channel Tunnel

In a statement in the House of Commons on July 1, the Minister of Transport, Mr. E. Marples, announced that the British and French Governments had decided that the further geological survey for the Channel tunnel should begin this summer. Arrangements were being made for the Channel Tunnel Study Group to conduct the survey on an agency basis under the general supervision of the British and French Governments, who were to appoint a Joint Commission of Surveillance for this purpose. Half the cost, which was expected to be about £1·25 million, would be met by the British Government and half by the French Railways which, at the instance of the French Government, were participating in the contractual arrangements. The survey arrangements were entirely without prejudice to decisions yet to be made by the Governments on the organization and financing of the project, but it was the present intention of both Governments that eventually the cost of the survey should be charged to whatever organization might be set up for the tunnel itself. Mr. Marples added, in reply to questions, that this was the first of many investigations which would have to be made before the tunnel was built. In the House of Lords, on the same day, Lord Chesham said that Col. D. McMullen, chief inspecting officer of railways in the Ministry of Transport, would be co-chairman of the Joint Commission of Surveillance, of which Dr. C. J. Stubblefield, director of the Geological Survey, would also be a member. He hoped that the survey would be completed within a year.

Problems of Water Supply in Britain

In reply to a question in the House of Lords on July 15, the Joint Parliamentary Secretary, Ministry of Housing and Local Government, Lord Hastings, said that large quantities of water were already being obtained by exploiting the natural storage capacity of underground aquifers, but in some areas their full capacity was unknown or not fully utilized. The Thames Conservancy was exploring the potentialities of the chalk in the Thames Basin, and since the publication of *The South-East Study, 1961–81*, a preliminary investigation of the chalk in the Great Ouse Basin had been arranged. The Water Resources Board and the new river authorities would investigate the suitability of geological conditions in Britain for the large-scale use of artificial recharge to augment natural storage capacity, but he did not think that this could be a complete panacea for all water supply problems. In a written answer in the House of Commons on July 16, the Secretary of State for Industry, Trade and Regional Development, Mr. E. Heath, stated that if the preliminary assessment now being made by the North-West Study Group of the suggested Morecambe Bay and Solway barrage schemes showed that the expenditure would be justified, the examination would include a full technical and economic investigation of these projects.

Large-scale Distillation and De-salting Plants

Replying to a question in the House of Lords on July 15, the Joint Parliamentary Secretary of State for Education and Science, the Earl of Bessborough, said that the Atomic Energy Authority's preliminary investigations of the use of nuclear reactors for providing heat for sea-water utilization plants indicated that, to be economic, the reactors would need to be very large, and this function would have to be combined with the production of electricity. In addition to producing base load electricity, such a reactor station might provide a considerable quantity of fresh water as a by-product at a price within the range of interest for domestic and industrial users in certain areas. The necessary continuous demand for electricity on a large scale limited the number of areas in which such dual-purpose reactors could be economic. Further development in the technology of de-salting plants was required and the Authority was in close touch with the Department of Scientific and Industrial Research. It was also represented on the panel of experts set up by the International Atomic Energy Agency to investigate the possibilities of these plants in developing areas. British industry was taking a leading part in the construction of large-scale distillation plant and provided some 70 per cent of land-based plants in the world.

Planning and Amenities

The annual report of the Sheffield and Peak District Branch of the Council for the Preservation of Rural England directs attention to ways in which the importance of the preservation of amenities, in central planning, is being undermined (Pp. 26. Sheffield: Council for the Preservation of Rural England. Sheffield and Peak District Branch, 1964). Difficulties of æsthetic control were aggravated by the Central Development Order of 1950, and in the same year the Schuster Report tended to lessen the importance of æsthetics in the training of qualified officers. Another serious blow followed in 1951, when the word 'Planning' was left out of the Ministry's title and "The order and seemliness striven for so long began to disintegrate again". Now, alarmed by the unexpected rise in population, the Minister has hinted that 'Green Belts' are not inviolate, and has thus loosened the restraints on ill-sited development of rural land in a way that may be bitterly regretted by coming generations. "We are thus losing at a greater pace than ever a countryside that has been called 'the loveliest in the world' ". Now, at last, influenced by experienced planners, we are beginning to recognize that regional planning is a necessity. "This has been not unfavourably received by urban authorities, so long as it is understood that their own town or city should be the central influence in the region."

British Mammals

The Identification of British Mammals, by G. B. Corbet, published by the British Museum (Natural History), is an excellent guide to the classification and identification of the sixty-odd species of mammals found in the British Isles (Pp. iii+46. London: British Museum (Natural History), 1964. 4*s*.). It is intended mainly for the amateur naturalist, but will be equally useful to the professional zoologist. The principles of classification are first explained and then follows a list of the British mammal fauna, giving the synonymy and status of each species. The main part of the pamphlet consists of keys for identifying the different species by external features—field identification is not included. There is an interesting list of possible additions to the fauna, a select bibliography, and a good index.

The Geological Museum, London

The fourth edition of *A Short Guide to the Exhibits* of the Geological Museum in South Kensington starts with a brief history of the Museum and then gives a summary of the general arrangement of the exhibits (Pp. 36. London: H.M.S.O., 1964. 2*s*. 6*d*.). The visitor is then taken on a short tour of the galleries and is thus able to obtain a broad idea of the scope and nature of the display collections. The well-known dioramas in the Museum are illustrated, and with these and other pictures even a visitor not acquainted with geology should be able to view the exhibits intelligently. The text of this useful and handy pamphlet is clearly written, with few technical phrases.

Nuclear Magnetic Resonance Current Literature Service

A new literature searching service, dealing with papers on nuclear magnetic resonance, nuclear quadrupole resonance and electron paramagnetic resonance, is to be established by Butterworths, the publishers of *Documentation of Molecular Spectroscopy*. This will take the form of a numbered and coded literature list which is searched by means of a peep-hole index of coded punched cards. The coding has been devised to enable searches to be made from two main starting points: (1) from the general contents of the paper, the nature of the problem investigated, and details of the techniques and apparatus described; (2) from the chemical classification of the compounds examined. The literature lists will give the title, author, journal or other source of publication, date and other relevant information, including, where necessary, a brief note on the content. It is hoped that, as they will be issued four times a year, they will offer: (*a*) an up-to-date and comprehensive source of rapid information which is easily retrievable by the use of the peep-hole index containing 105 cards per issue; (*b*) a current documentation of the entire field of magnetic resonance spectroscopy. At the end of the subscription period of two years the peep-hole index cards provided with each issue will be replaced by a consolidated peep-hole card index, thus making possible the searching of the literature in compact two-year batches. An alphabetical list of authors will also appear. A detailed *Instruction Manual* will be provided giving particulars of the coding. The service will cover the literature published since the beginning of 1963. It is also planned to produce, in due course, a collection of references covering the years 1946–62. A service similar to that described here, but covering infra-red, Raman and microwave spectroscopy, has been in operation as part of *Documentation of Molecular Spectroscopy* since the beginning of 1963. This is supplied to subscribers as part of their subscription but is also available separately. Full details of these services are available from Butterworths, 88 Kingsway, London, W.C.2.

University News: London

Dr. A. O. Betts, University lecturer at the School of Veterinary Medicine, Cambridge, has been appointed to the chair of veterinary microbiology and parasitology at the Royal Veterinary College. Dr. J. Edelman, reader in enzymology at the Imperial College of Science and Technology, has been appointed to the chair of botany at Queen Elizabeth College. Dr. F. G. Foster, reader in statistical computing at the London School of Economics and Political Science, has been appointed to the chair of computational methods at that School. Dr. W. W. Schwabe, a member of the staff of the Agricultural Research Council Unit of Plant Morphogenesis and

Nutrition at Wye College, has been appointed to the chair of horticulture at that College from October 1, 1965. Prof. R. A. J. Coutrez, "Professeur extraordinaire" at the Free University of Brussels and astronomer at the Royal Observatory of Belgium, has been appointed Belgian Visiting Professor for the session 1964–65.

Oxford

THE annual report of the Curators of the Bodleian Library for the year ended July 31, 1963, refers to the completion of the structural work on Duke Humfrey's Library early in 1963 (Supplement No. 9 to the *University Gazette*, May 1964. Pp. 43. Oxford: The University, 1964. 2*s*.). Attention is directed to the progress of development and rearrangements which will greatly increase the efficient administration of the Library and provide space for 24 more readers, if alternative exhibition rooms are found in the Divinity School and the Proscholium is converted into a new entrance hall serving both the Divinity School and the Old Library. The annual grant from the University General Fund was £221,644, nearly £9,000 less than the previous year; but the 107,071 books and manuscripts fetched for readers and 28,653 for staff represents an increase of more than 20,000. Accessions to the Department of Printed Books totalled 44,826 volumes and 121,276 parts, compared with 44,203 and 115,844, respectively, in the previous year.

The Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme

AWARDS under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made as follows: Dr. Margaret C. Anderson, Botany School, Cambridge, to enable her to work on light penetration at various levels in pine forest in the Section of Agricultural Physics, C.S.I.R.O. Division of Plant Industry, Canberra, for about five months from November 1964; Dr. R. L. W. Averill, senior research officer, New Zealand Medical Research Council's Department of Endocrinology Research, to assist him to learn techniques of hypothalamic investigation at Oxford, for ten months during 1964–65; Dr. D. J. Eve, lecturer in chemistry, University College of Rhodesia and Nyasaland, to enable him to carry out research on the spectroscopic characterization of inorganic co-ordination compounds at Southampton, from September 1964 until June 1965; Dr. K. M. King, associate professor, Soils Department, Ontario Agricultural College, to enable him to study in the field of micrometeorology and evaporation at the C.S.I.R.O. Division of Meteorological Physics, Melbourne, for five months from December. Dr. Alicja M. Kirkien-Konasiewicz, lecturer in chemical engineering, University of the West Indies (Trinidad), to enable her to learn techniques in high-resolution mass spectrometry at University College, London, from January until April 1965; Dr. S. E. Livingstone, associate professor of inorganic chemistry, University of New South Wales, to assist him to work in the field of co-ordination chemistry at University College, London, for nine months from September; Dr. B. Morris, Professorial Fellow, Department of Experimental Pathology, Australian National University, Canberra, to enable him to investigate at Oxford the role of the lymphatic system in the absorption of fat in fishes, for six months from September; Prof. K. C. Mukherji, professor of electrical engineering, Indian Institute of Technology, Bombay, to enable him to carry out investigations on electrical machines at the University of London King's College, for a year from October; Prof. R. A. Reyment, professor of geology, University of Ibadan, to assist him to study the ostracods of the marine Tertiary of Australia, for three months in the autumn; Dr. G. G. E. Scudder, assistant professor of zoology, University of British Columbia, to enable him to acquire knowledge of type material of Rhyparochrominae and techniques for insect blood analysis at the Imperial College of Science and Technology, London, for a year during 1964–65; Dr. R. L. Stanton, senior lecturer in geology, University of New England, to enable him to examine naturally deformed sulphide ores, at Imperial College of Science and Technology, London, and Durham, from September until November, in connexion with investigations on the significance of surface tensions in the final development of grain shapes in such ores. Dr. L. B. Thrower, senior lecturer in botany, and Mrs. S. L. Thrower, senior demonstrator in botany, both of the University of Melbourne, to assist them in their investigations on the effect of sporulation on the pattern of movement of nutrients in fungal hyphæ at Birkbeck College, London, and to attend a course on radiobiology, and to enable her to investigate the physiology of lichen growth at Birkbeck College and the British Museum (Natural History) during 1965.

Announcements

PROF. F. G. YOUNG, Sir William Dunn professor of biochemistry in the University of Cambridge, has been appointed the first Master of the newly formed post-graduate Darwin College at Cambridge. Prof. Young is president of Section I (Physiology and Biochemistry) at the Southampton meeting of the British Association for the Advancement of Science (see p. 952 of this issue of *Nature*).

AN index to the survey *Manchester and its Region*, prepared for the British Association meeting held in Manchester in 1962 (*Nature*, 195, 890; 1962) has now been compiled by the Manchester and District Division of the Association of Assistant Librarians under the editorship of Mr. M. J. Harkin. To the public spirit of him and his colleagues warm thanks are due from all who appreciate the merits of the admirable survey originally issued for the British Association by the Local Committee.

THE fourth Louis Rapkine Memorial Lecture entitled "La Proliferation et Differenciation des Cellules Hematopoietiques" will be delivered by Dr. Louis Siminovitch (Ontario Cancer Research Institute) at the Pasteur Institute, Paris, on October 7.

A CONFERENCE on "Electron Emission", arranged by the Electronics Group of the Institute of Physics and the Physical Society, will be held in the University of Keele during October 1–2. During the conference, the Guthrie Lecture for 1964 will be delivered by Prof. Martin Ryle. Further information can be obtained from the Administration Assistant, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE National Conference of Food Hygiene, organized by the Institute of Nutrition, Budapest, will be held in Budapest during October 29–31. Topics under consideration will include: the effect of extraneous substances in food on the human organism; the hygiene problems of pesticide residues; the hygiene problems of contaminants of technical origin (metals, plastics). Further information can be obtained from the Institute of Nutrition, Gyáli ut 3/*a*, Budapest IX.

THE annual meeting of the American Documentation Institute on "Parameters of Information Science" will be held in Philadelphia during October 5–8. Subjects under consideration will include: symbolization and transformation of information; information-seeking behaviour; information in decision procedures; analysis, correlation and indexing; document media, storage and display; memory organization and search; information sciences; goals in education; the profession; information centres and networks. Further information can be obtained from A. W. Speakman, American Documentation Institute, 2000 P Street, N.W., Washington, D.C. 20036.

AUTOMATION, LEISURE AND YOUTH SERVICES

TWO short debates in the House of Commons on June 19 and June 22 complement earlier debates in the House of Lords on automation on April 8 and on the problem of leisure on May 13 (see *Nature*, 202, 629; 1964; and 203, 1; 1964). In the first of these debates, a motion of Mr. C. Curran was agreed, calling on the Government to state its policy for improving still further the educational facilities provided for less-gifted children who may otherwise be excluded from an automated labour market. This motion had been framed in view of the social consequences that follow when automation increases production by using a smaller labour force and when people below a certain minimum standard of ability and education may consequently find it hard to obtain employment. As the motion indicates, Mr. Curran was concerned with the social consequences of automation and with the less-able children with whom the Newsom Report was specially concerned (see *Nature*, 201, 1; 1964). He thought it would be most unwise to limit their secondary education to technical instruction: lack of literacy and the ability to communicate was likely to be a much more serious handicap to them than any lack of acquired skill. This found strong support in the debate; for example, Colonel Sir Harwood Harrison paid a warm tribute to the work of the county civic colleges, and pointed out that all education should seek to help a boy or girl to live a fuller life and to be more self-reliant. Mr. R. E. Prentice stressed the need to develop within the framework of Government techniques of forecasting man-power which would enable us to discern where redundancies and shortages were likely to occur. Britain's education and training policies should be geared to this kind of forecasting. He anticipated in future a much larger demand for skill and education in the working population as a whole and thought that there was much potential talent at present unused. He urged the importance of expanding the youth service and asked whether the Government had accepted the interim target of an increase of 50,000 day-release places a year for the next five years recommended by the Henniker Heaton Committee of the Ministry of Education. Mr. Dudley Smith, like Mr. Prentice, referred to the importance of leisure and sport, stressing the need to inculcate a better sense of civic purpose and responsibility in the community as a whole, while Sir Barnett Janner described the successful working of youth clubs in Leicester.

The Joint Under-Secretary of State for Education and Science, Mr. C. Chataway, replying on the debate for the Government, while welcoming the motion, discounted the idea that automation was likely to lead to any serious shortage of work. After referring to the work of the Interdepartmental Committee dealing with the general theme of 'the schools and society', Mr. Chataway said that one of the tasks of the new Schools Council, to be set up as an independent representative body with Sir John Maud as chairman, would be to foster the circulation of ideas in the schools. Its first meeting would be in October and the main function of the body would be to keep under review curricula, teaching methods and examinations in Britain's primary and secondary schools. He thought that the new Council was likely to stimulate much more research and development, and he pointed out that the context within which the recommendations of the Newsom Report must be pursued had been subtly altered by the Government's acceptance of the main recommendations to raise the school-leaving age. He also stressed the importance of the problem of relevance between school and work. Much more was now required to bridge the gap between school and work, and he thought a major co-operative effort involving the Government, trade unions, employers and many other bodies and organizations, besides the Schools Council, was needed if this problem was to be tackled seriously. We should know much more than we do about the qualities school leavers ought to possess if they were to move easily from school to work and from one form of employment to another in later life.

In opening the debate on leisure and sport, Mr. J. P. W. Mallalieu pressed for better facilities for enjoying all forms of leisure. Besides greater support for the National Playing Fields Association, the Central Council for Physical Recreation and the Youth Hostels Association, as well as for music and drama, he pressed for more regional surveys of the needs and facilities for enjoying leisure, but centrally co-ordinated. Mr. Chataway, who followed, said that the building programme for youth clubs was now running at £4·5 million a year, compared with less than £1 million before the Albemarle Committee Report, and by this spring about 700 projects had been finished. By midsummer 1963 Britain had nearly 1,000 youth leaders against the target of 1,300 set by the Albemarle Committee for 1966 and a further 200 were in training at recognized centres. A major need was to widen the appeal of the Youth Service and to devise and extend new approaches to the less purposeful kind of youths. Since 1960–61, capital expenditure on facilities for sport and recreation had risen from £5·6 million to an estimated £22·5 million in 1964.

In replying to a later debate, the Secretary of State for Science and Education, Mr. Q. Hogg, referred to the importance of seeing that, when Government expenditure on youth services was increased, it was done so intelligently and purposefully. Discussing Mr. Mallalieu's suggestion for a senior Cabinet Minister responsible for leisure, Mr. Hogg thought that this was unlikely to provide a satisfactory solution to the problem. He had originally been attracted by the idea of a sports development council, but now was moving away from it—for administrative reasons. He thought that the present arrangements, with a small central organization to co-ordinate the work of the voluntary bodies. the local education authorities and Government departments had won general confidence and were working well. Developments had been rapid both on the arts side and in sports. Expenditure on the arts had risen from £3 million in 1951 to £13·5 million, and developments in museums, entertainments, adult education and educational broadcasting had enlarged almost beyond recognition the spectrum of culture and recreation in leisure in Britain. On sport, he said that there was a more liberal policy of grants and capital expenditure to amateur sports clubs; these grants are now available to single-purpose, and not, as before, multi-purpose authorities. Grants to composite bodies, such as the Councils for Physical Recreation and National Playing Fields Association, were increasing and Britain had liberalized her loan policy to local authorities. It was also hoped to have a series of sports development councils on a local basis throughout Britain.

THE MELLON INSTITUTE, PITTSBURGH

THE fifty-first annual report of the Mellon Institute, Pittsburgh, covering the year ended February 29, 1964*, includes the usual list of publications and records expenditure on independent and sponsored research amounting to 6·4 million dollars. At the end of the year the Institute had a staff of 541, including 347 professional and technical workers. During the year arrangements were made for much closer working with the Carnegie Institute of Technology and the University of Pittsburgh: a non-profit corporation was formed under their joint sponsorship, with the major objective of promoting closer contact and co-ordinated efforts among members of the staffs and local industry.

In theoretical chemistry, the judicious application of the principles of molecular orbital theory and its simplification, ligand field theory, can yield a striking clarification of the various colours exhibited by transition metal ions with the architecture of the crystal lattices housing them. Work on the nature of a chemical binding in transition metal cyanides has been resumed and a general investigation initiated of the relative placement of energy-levels in other families of transition metal elements. In continuum physics, mathematical methods were developed for finding the restrictions which the Second Law of Thermodynamics places on constitutive equations, and solutions have been obtained for some unsteady flow problems in the theory of a second-order fluid, a fluid the behaviour of which approximates that of general viscoelastic fluids in slow flows. The coefficient of thermal expansion was determined for several copper germanium alloys with hexagonal close-packed structure by investigating their lattice spacings as a function of temperature between 24° and 600° C. The influence of temperature, strain rate, and interstitial impurities on the plastic deformation of poly-crystalline niobium has been investigated, and results from a thermal activation analysis supported the view that the mechanism controlling the rate of flow of dislocations at low temperatures is that of overcoming the Peierls–Nabarro barrier by the nucleation of kinks on dislocations. Electron spin resonance investigations continue to provide very detailed information on the structure of free radicals. An investigation of internal rotation in molecules by low-frequency infra-red spectroscopy has taken two new directions, one involving torsions of methyl groups attached to a phenyl ring, and the other, torsions round the central single bond in the butadiene glyoxal and acrolein systems.

A new vacuum ultra-violet spectrophotometer with low dispersion is being used to obtain the absorption spectra of systems which have electronic transitions of interest beyond the range of most commercial instruments. Studies on the chemical bonding of *tris*-2,2-dipyridyl complexes with transition metal ions in unusual low oxidation states continued, while an investigation of the different intermediate products isolated during the chemical or electro-chemical reduction of solutions containing tungstates was started. In a direct investigation of hydrogen content of acidic catalysts, it was found the total hydrogen content could be accurately determined by exchange with deuterium. The isomerization of *cyclo*propane to propylene has been examined over series of alumina and silica–alumina catalysts, and spectroscopic investigations of the chemisorption of triphenylmethane and of polynuclear aromatic hydrocarbons continued.

Other work was concerned with the total synthesis of diterpenes and diterpene alkaloids, and the effect of ring size on the nuclear magnetic resonance shifts of the saturated cyclic hydrocarbons from *cyclo*propane to *cyclo*heptodecane was investigated. A survey of the chemical and physical characteristics of the asphaltic fractions of some 40 crude oils and other bituminous materials was completed, while a broad research programme of the separation, concentration and identification of volatile components of potential food flavour import was continued. A soluble poly-*cyclo*pentadiene of relatively high molecular weight has been obtained using a new homogeneous catalyst system conveniently formed *in situ*, and the theoretical investigation of branched polymers in dilute solution was extended to include a statistical mechanical calculation of the second virial coefficient in the equation of state for 'comb' molecules. A detailed investigation was undertaken of the crystallization, kinetics and morphology of poly (tetramethyl-*p*-phenylene) siloxane. A rapid method of electrophoresis on cellulose acetate strips has been found for developing the electrophoretic components of brome-grass mosaic virus.

MIRIDS AND OTHER INSECT PESTS OF COCOA

IN view of the common problems which prevail in the field of agricultural research in West Africa, the Governments of the then British and French Territories decided to institute a series of conferences on cocoa (*Theobroma cacao* L.), oil palms, rice, groundnuts and other crops to which the Belgian, Liberian, Portuguese and Spanish Governments would be invited. The first of these conferences was on cocoa and was held at the West African Cocoa Research Institute (now Cocoa Research Institute (Ghana Academy of Sciences)) at Tafo in Ghana in December 1953 (ref. 1). Apart from a conference on Cacao Breeding[2], held in Ghana in 1956, no further conferences on cocoa occurred in this series until August 1963, when a conference on Cacao Mirid Control[3,4] was held in Ghana. At this conference information was released on the existence within Ghana of populations of the mirid (= capsid) *Distantiella theobroma* (Dist.) (Hemiptera; Miridae) resistant to lindane (gamma-BHC) and to other *cyclo*diene insecticides.

At the same conference, data suggesting the existence within Nigeria of a similarly resistant mirid, *Sahlbergella singularis* Hagl., were presented. *D. theobroma* and *S. singularis* being the most important insect pests of cocoa in West Africa, it was the feeling of the 1963 conference that the problems of resistance and control should be the subject of another meeting in March of the following year when the results of experimental work in the intervening season of high mirid populations would be available. The opportunity was also taken to include other insect pests of cocoa, and the conference was held during March 24–27, 1964, at the West African Cocoa Research Institute (Nigeria) at Ibadan, Western Nigeria. In view of the prevalence of mirid attack on cocoa in many producer countries outside Africa and of other common entomological problems, this conference was given an international bias.

The emphasis of the conference was naturally on mirid resistance and control, but Mr. P. F. Entwistle and Mr. A. Youdeowei presented a general, but preliminary, world review of cocoa mirids. Attack on cocoa by a mirid (*Helopeltis antonii* Sign.) was first noted in Ceylon in 1863 (ref. 5), and since then at least 34 more species have appeared on cocoa throughout the world. The only significant producing area which appears to have remained entirely free from attack is the Caribbean archipelago. New adaptations of mirids to cocoa have occurred in recent times; for example, during the past ten years, five species have appeared on cocoa in the Territory of Papua and New Guinea (1954–57), one species in Madagascar (1960), and two species in the State of Sabah (Malaysia) (1961–62). In addition, *H. antonii* appears to have been completely replaced on cocoa in Ceylon by *Helopeltis ceylonensis* De Silva, a species not described until 1957. *S. singularis*, which at one time appeared to be the dominant species in Ghana, has, since the wide-scale use of lindane, become much less common than *D. theobroma*[4]. This dynamic situation extends to behaviour within the crop; for example, *D. theobroma*, which now attacks both mature and seedling trees, was at one time restricted to seedlings. It is not easy to make a world assessment of the status of mirids as pests, but there is little doubt that attack is most severe in West Africa. In the New World, attack tends to be locally restricted, and this is also true of Papua and New Guinea and of Sabah, but not of Ceylon and Java, where attack is by species of the genus *Helopeltis* (which have a very wide host–plant range).

Mr. G. R. Conway reported that in Sabah a hitherto undescribed mirid species, *Platyngomiriodes apiformis* Ghauri, and *Helopeltis clavifer* Walk. (which first attacked cocoa in Papua and New Guinea in 1954), has recently begun to attack cocoa. *P. apiformis* initially confined its attacks to pods, but later began to damage stems severely and is considered a potentially more serious pest than *H. clavifer*. Mr. G. S. Dun submitted notes on a list of 249 cocoa pests in the Territory of Papua and New Guinea, prepared by Dr. J. J. H. Szent-Ivany, among which were five species of mirids which did not begin to attack cocoa until 1954.

Mr. M. Wessel presented a paper on the climate of the cocoa-growing areas of Western Nigeria, in comparison with some other producer countries in West Africa, which provided a necessary background to discussion of species distribution and the design of regionally adapted spray programmes. M. J. E. Decelle and Dr. G. Nonveiller reported there was no resistance in the Ivory Coast or Cameroun, though one population of *D. theobroma* in the Ivory Coast showed a bimodal distribution of kill when exposed to *cyclo*diene insecticides. Mr. J. N. Telford said *D. theobroma* was found to be resistant in a large area of Ghana comprising a portion of Ashanti and Eastern Region and also in a number of smaller isolated areas within these two Regions. The intensity of resistance had not been fully measured, though three areas tested contained 90–100 per cent resistant individuals. While no indication of resistance in *S. singularis* had been found in Ghana, Mr. Entwistle reported that a population of this species containing resistant individuals has been located in Western Nigeria. *D. theobroma* occurs sparingly within the area of resistance of *S. singularis* in Nigeria, but does not itself appear to be resistant.

In the Ivory Coast, M. Decelle reported that nine phosphoric esters were tested in the laboratory on cocoa mirids and the action of dichlorovos (DDVP) was noted to be particularly fast, though in comparison with 'Sumithion' it gave poor control in field trials at 0·3 per cent. Mr. G. Prins described the laboratory assessment of 16 organophosphates, five carbamates, one vegetable and one vegetable insecticide plus a synergist sprayed on to various parts of anæsthetized fourth and fifth instar nymphs of *D. theobroma* in Ghana. He assessed his results by the

$$\text{'Index of effectiveness'}\left(= \frac{\text{oral } LD50 \text{ to rats}}{LD50 \text{ to insects} \times 1{,}000}\right)$$

which is an attempt to combine safety to humans with insecticidal activity, and is used primarily by the United Nations World Health Organization. He found eleven compounds to have a higher index than lindane. Dr. B. M. Gerard suggested that 'index of acceptability' would be a better name and thought it best to ignore the index altogether when the insecticide is 'obviously safe', and to consider only its efficiency and cost. On this basis, and from some additional data, Dr. Gerard considered only seven or eight of these candidate compounds worthy of field tests.

Dr. D. G. Peterson and Mr. E. F. Bond described the final phase of their field control experiments in Ghana with 'Sumithion' and carbaryl ('Sevin 85-*S*') which, when applied by motor-powered knapsack machines adjusted to deliver 0·19 gal. per min, were equally effective, in contrast to laboratory findings which suggested that, when applied in acetone solution, carbaryl has eight times the efficiency of 'Sumithion'. In Nigeria, Mr. Entwistle, Mr. Youdeowei and Mr. W. Eguagie conducted trials with these two insecticides applied with pneumatic knapsack machines fitted with spray lances 5 ft. long, a type which many farmers already possess. These machines have a shorter distance of throw (about 5 ft. with the model used) and distribute the spray deposit less satisfactorily than motor-powered ones. Two oz. carbaryl or 1 oz. 'Sumithion' in 5 gal. water per 100 trees gives approximately 86 per cent control. At the same toxicant level, but at lower volumes, less control was achieved, and increasing the toxicant by 50 per cent, at the 5-gal. rate, did not appear to improve control. Hence volume, probably as coverage, seems to be the limiting factor.

Dr. G. E. Marshall commented on some of the problems inherent in the conduct of mirid control trials. Among variables are the mechanically disturbing effect of counting on mirid populations, recorder and spray application efficiency and differences in coverage resulting from the use of different types of machine. He pointed to the necessity for developing both intra- and inter-nationally standardized experimental procedures which will allow a comparison of findings. There is a need for developing additional screening steps between purely laboratory assessment and full-scale field trials.

Extension work in mirid control was described by Mr. J. O. Akinwolemiwa for Western Nigeria, where 600,000 farmers have been trained in mirid control during 1956–63, and by Dr. Nonveiller for Cameroun, where the 1964 anti-mirid campaign is designed to treat 350,000 acres.

Dr. J. Miyamoto reported that the poorer penetrability of 'Sumioxon' than methylparaoxon (the oxygen analogues of 'Sumithion' and methylparathion) into brain, together with the poorer formation of acid-precipitable phosphorus therein, were assumed to be the main factors in reducing the toxicity of 'Sumithion'. M. Decelle reported that carbaryl and 'Sumithion' caused no alteration in cocoa flavour, but that "three or four tasters", out of a total of "22–24", showed slight allergic reactions after tasting the 'Sumithion'-treated samples.

Mr. Youdeowei reported on progress in the development of artificial methods of rearing mirids (particularly *S. singularis*) in Nigeria, work which is of importance not only for the investigation of the genetics of resistance to insecticides, but which could also provide a supply of mirids for laboratory work at times of the year when they are scarce in the field.

Experiments in Ghana, where most of the cocoa is grown beneath the shade of forest trees, have shown that shade removal leads quickly to greatly increased yields[6]. Dr. Gerard presented a paper on the insect pests of unshaded cocoa in Ghana and advised that before widespread shade removal is recommended its side-effects should be investigated on large trial plots.

Mr. W. R. Ingram described the development of injurious infestations of the aphis *Toxoptera aurantii* B. de Fon. on seedlings in nurseries in Uganda, which he thought might be partially attributed to the previous use of DDT to control caterpillars. Menazon, a systemic insecticide, applied at 0·25 per cent, gave excellent control.

Mr. C. O. R. Everard assessed the rodent problem on cocoa in West Africa. Most losses were of pods from the trees rather than during drying or in storage. Under conditions of good husbandry pod losses should not normally exceed 3 per cent. The use of the most efficient traps available would be unlikely to reduce losses appreciably, and probably the best means of protection lies in the use of relatively non-toxic repellents applied directly to the pods.

The working session on the final day of the conference concerned itself mainly with plans for the future, and it was agreed that entomologists at present concerned with experiments in mirid control in West Africa would communicate further with the view of developing standardized systems for evaluating candidate insecticides in the field and, if possible, for sharing some of the labour involved in the conduct of tests designed to provide fermented and dried samples of beans for taint and toxic residue tests. An appeal was made to the manufacturers to develop methods which would allow the use of smaller samples in taint tests, and embody greater accuracy. Some problems could not be dealt with on a joint basis, for example, testing candidate insecticides for their effects on population-levels of other insect pests. Insects normally of only minor importance have been known to increase to pest status on cocoa following applications of insecticides[7]. While several of the species involved occur throughout West Africa, parasite and predator complexes of some of these have been shown to differ regionally. Population increases resulting from the removal of such biological restraints will vary with the effect of insecticides on the particular species complex concerned.

Delegates to the conference visited the Institute's experimental station at Gambari, twelve miles from Ibadan, where spraying machinery and methods in use in Nigeria were demonstrated and local entomological problems illustrated in the field.

The *Proceedings* of this conference will shortly be available from the Secretary, West African Cocoa Research Institute (Nigeria), P.M.B. 5244, Moor Plantation, Ibadan, Nigeria.

SOIL—PLANT—ANIMAL COMPLEX

A MEETING of the Nutrition Society was held in the University of Reading on July 17 under the chairmanship of Prof. R. G. Baskett (National Institute for Research in Dairying, Shinfield). This meeting took the form of a symposium entitled "The Effects of Soils, Fertilizers and Environment on the Yield and Nutrient Content of Plants". In his introductory remarks, the chairman mentioned that the subject of the symposium was something of a departure from the range of subjects normally discussed by the Nutrition Society, but it was clear from the reactions of members and guests throughout the meeting that they considered it entirely appropriate that nutritionists should concern themselves with problems of food production.

The first paper of the day was one by Prof. J. N. Black (Edinburgh) on "The Ultimate Limits of Crop Production". He began by reviewing the major factors limiting the yield of plants which have been emphasized in the past—soil fertility, including nutrient status, temperature, water supply, pests and disease and the genetic make-up of the plant. He continued by asking the question "If it were possible to remove all the factors acting to maintain yields at a low level, what would then determine yield and what might the yield then be?". The significance of this question lies in the fact that, if answered, it would provide a yardstick with which to measure the efficiency of an agricultural system and the rate of progress of improvements in technique. Recent work on the efficiency of the photosynthetic process was then discussed, culminating in the conclusion that, in the absence of other limiting factors, the productivity of crop plants is determined by the amount of solar radiation available. The complex interrelationship between solar energy, leaf area index (the ratio of leaf area to ground area) and crop-growth rate and ultimate yield was emphasized, and the necessity for interpreting the results of field trials, involving fertilizer and other treatments, in the light of these relationships was stressed.

In his paper on irrigation as a factor in increasing food production, Dr. H. Olivier (Sir Alexander Gibb and Partners) surveyed the history of irrigation practices from pre-historic times up to the present day, followed by a critical assessment of the potential increase in food production in selected countries and regions in relation to their land and water resources.

The vital role of increased irrigation in increasing crop production in arid and semi-arid countries was emphasized. Nevertheless, doubt was expressed as to whether present nutritional standards could be maintained in many of these countries if the present-day population forecasts turn out to be correct, even if potentially irrigable land and water supplies are fully exploited. The considerable value of supplemental irrigation for increasing crop production in countries such as the United States and Western European countries, including the United Kingdom, is much less generally recognized and it is a technique which no country in the humid zone can afford to neglect.

Dr. Olivier ended his paper by considering the present outlook for food production and concluded that no reliable estimate of world potential was possible at present owing to a lack of basic information on such vital matters as potential agricultural land and effective rainfall, particularly in areas where the most serious food shortages occur. He stressed the need for the extension of soil surveys, for the reorganization of meteorological observations to make them more meaningful for agricultural purposes and for the compilation of statistical data on crop yields by region and by soil types.

The relationship between plant nutrient content of soil and leaves and crop yield was discussed by Dr. C. Bould (Long Ashton Research Station). He began by summarizing the present state of knowledge concerning the factors affecting the availability to plants of the inorganic ions in the soil and outlined the difficulties inherent in chemical methods of assessing the nutrient status of soils. A biological method, namely leaf analysis, has been shown to provide a more reliable assessment of plant nutrient availability. It is possible to establish for many species a range of nutrient concentrations at specific stages of growth associated with gross deficiency, marginal supply and sufficiency, based on crop yield. However, it is not yet possible to predict how much fertilizer is required to raise the nutrient status of a crop from deficiency to sufficiency, although this may be possible when more precise information relating soil nutrient status to plant nutrient content is available for different soils and crops.

Prof. A. H. Bunting (University of Reading) read a paper on "Effects of Organic Manures on Soils and Crops", and presented strong evidence derived in part from the results of more than 100 field trials conducted from the Rothamsted Experimental Station that the effects on crop yield of organic manures based on straw are for the most part produced by the plant nutrients which the manures contain. On soils which tend to compact, strawy manures, but not sewage sludge, increase the yield of crops to a greater extent than can be explained by their content of plant nutrients. This appears, as work at the National Vegetable Research Station, Wellesbourne, and Rothamsted Experimental Station has shown, to be the consequence of a change in the geometry of the soil which prevents it from compacting and increases the volume of larger pores, and consequently the amount of water which can be held at low tension. In ley fertility experiments, the effects of leys on subsequent crops have proved to be largely due to increases in the supply of plant foods rather than to increases in the proportion of water-stable crumbs. Organic matter *per se* does not appear to have any special properties influencing crop yield except on special soils where the effects are shown only by particular types of organic matter. It is now important to concentrate experimental work on these special soils (which are thought to occupy about one-tenth of the arable land of England), using factorial experiments so designed that the effects of nutrients can be measured separately.

The final paper was one by Dr. R. Waite (Hannah Dairy Research Institute, Ayr) on "The Chemical Composition of Grasses in Relation to Agronomical Practice". He emphasized that modern techniques of grassland management have resulted in greatly increased yields of digestible nutrients and presented data from his own experiments carried out at the Hannah Dairy Research Institute on the changes in composition of leafy herbage from several species of grasses during the growing season. The most significant change was in the fructosan : protein ratio, which was high in the early part of the season and low in the autumn. The former type of herbage would be expected to promote a predominantly propionic acid type of rumen fermentation, which would stimulate the production of non-fatty solids in the milk of cows and promote fattening in beef animals. Herbage low in soluble carbohydrates, on the other hand, would encourage an acetic acid type of fermentation in the rumen and the resulting mixture of volatile fatty acids would be used more efficiently for butter-fat than for solids-not-fat production or for fattening. Herein may well lie the superiority commonly attributed to spring compared with autumn grass for fattening and milking animals.

The symposium ended with a summing-up by Prof. P. W. Arnold (University of Newcastle upon Tyne), who high-lighted the major themes from the various papers and directed attention to some of the important gaps in our knowledge of the way in which plants interact with their environment.

The majority of papers read at this meeting were mainly concerned with the quantitative aspect of the production of plant foods and, indeed, this aspect covers a vast range of problems. The qualitative aspect of the influence of the environment on plants for human and animal consumption is of at least equal interest to nutritionists and might well provide the subject for another symposium.

The re-statement at this meeting of the fundamental dependence of the animal kingdom on the plant was most salutary, and a reminder of the rate at which the total food requirements of the human population of the globe are increasing can never be given too often. It is clear, however, that basic information on the methods by which the production of plant foods can be increased by the use of fertilizers, by growing improved varieties of crops, by irrigation and by better husbandry is freely available. The application of this knowledge is largely a problem of administration, education, finance, power supply, engineering and industrial production, and the avoidance of famine in the latter quarter of this century depends on its solution. The outlook is not wholly depressing, for it has been estimated that by the adoption of improved agricultural techniques, including the more efficient use of water, it would be possible to double the present yield from each acre of land at present under cultivation.

T. G. TAYLOR

SEARCHING FOR CREATIVITY

THE search for creativity—in all its forms—would seem to be commendable and, indeed, of supreme importance for the future of man, yet, reviewing progress so far achieved, P. E. Vernon can rate it no higher than the "latest fashion in American educational psychology"[1]. Those who have interested themselves in the problem have been moved by the impression that the whole educational system fosters conformist attitudes among pupils and students, which gain further support from present-day intelligence and aptitude tests. Prof. Vernon doubts if these strictures necessarily apply to the selective tests of pupils in England and Wales at 11+ and 18+.

He refers to the work of Calvin Taylor, who, on the basis of a number of investigations, including some carried out on industrial and Air Force scientists, maintains that in adult life there is little association between productivity and originality, and previous educational achievement; in fact, the correlations between the results of tests for creativity on one hand, and intelligence on the other, are not greater than 0·2–0·4.

In this context, Prof. Vernon thinks that L. M. Terman's long-term follow-up of a group of children of high intelligence quotient merits attention, both because the test used—Stanford–Binet—was a good one, and because the scores obtained in tests in early youth have been compared with later achievement over the best part of a life-time. As a whole, the group has been very productive in the arts and sciences, although scarcely any member could be characterized as a genius. Here, intelligence is of some relevance, as it is in the findings of Terman and C. M. Cox that, from their biographies, few men in history of outstanding ability had an intelligence quotient below 120; while D. W. Mackinnon's results suggest that above a certain minimum figure, about 120, intelligence quotient plays a relatively minor part in creativity.

J. P. Guilford has carried out a long series of investigations of high-grade adults, and claims to have identified about 60 separate factors concerned with mental ability. Prof. Vernon questions the validity of these factors, partly because they have not received full confirmation from other workers but chiefly because he considers that in itself factorial analysis of mental quality cannot produce the answers unless the factors correspond with what is recognized as 'originality' in daily life.

Another series of tests, similar to Guilford's, has been applied by J. W. Getzels and P. W. Jackson, this time on young high-school pupils. In their case, one group in the top 20 per cent on creativity tests, but not of outstanding intelligence quotient, were compared with another group from the top 20 per cent for intelligence but not of outstanding originality. In scholastic achievement both groups did about equally well; but since, as Vernon points out, the intelligence quotient of the group of high creativity averaged 127, as against 150 for those of higher intelligence quotient, the finding is of limited significance.

In this survey, however, on personality traits and sociometric status, the group of superior intelligence quotient were rated by their teachers higher than the more creative, which leads Vernon to suggest that, in England and Wales, some of the more 'original' 18-year-olds may fail to find places at universities because they were unpopular with their head teachers, and not good mixers.

As C. Burt has pointed out, in the researches by Getzels and Jackson, correlations between separate tests for creativity were about on the same level as they were with intelligence tests, so that in those studies Vernon can find no evidence for a factor for creativity distinct from *g* and *v*. He doubts whether those for creativity cover more ground than the typical battery of tests for verbal intelligence, English and arithmetic already in present-day use. His main criticism, however, is that the tests which Getzel, Guilford and others have devised give no support to the assumption that they are valid for creativity in general: follow-up data are not available, and the gap between tests at about the time of entry to the secondary school and true creativity at the university is much too great.

As indications of originality, Prof. Vernon holds that tests like these scarcely go beyond empirical impressions which indicate that, in general, creative people tend to be rather solitary, independent, non-conformist, with strong drives and motivations on distant goals (Taylor); lone wolves with an overriding sense of the worth of their own ideas (Anne Roe); far more given to intuition than sensation type thinking, with a strong streak of femininity, often having suffered from unhappy childhoods and being rebellious at school and university (Mackinnon); and displaying humour and wit, while being unconventional in their attitudes and aspirations (Getzels and Jackson). Besides, such criteria fail to distinguish really creative people from rebels, delinquents, beatniks, introverts, idealists, etc. Prof. Vernon's opinion is that leisure time interests between 12 and 16, like scientific hobbies and research, poetry and artistic activities, may have some predictive value; but, altogether, efforts may be misdirected if they set out to assess creativity in general, for it may turn out to be strongly individual and specific.

In final conclusion, Prof. Vernon disclaims any desire to disparage research into the assessment of creativity, but in his mind the crucial problem is to devise tests which do not require a long follow-up. He feels that present appraisals by schools and universities are heavily biased in favour of conventional attainment, but research into home, leisure and educational backgrounds might be rewarding, and the influence of an inspiring teacher might be tremendously important.

RECORDINGS FROM SATELLITE *Alouette I*

A Very-low-frequency Plasma Resonance

AN unusual band of noise observed in the *Alouette I* satellite has been reported by Barrington and Belrose[1], who noted that the band had a sharp lower frequency cut-off which usually increased in frequency with decreasing latitude of the satellite. Since this lower cut-off frequency varies consistently with the location of the satellite, it is deduced that the observed changes in this frequency arise from spatial rather than temporal effects. Because the lower cut-off frequency is sharp and changes measurably within a few seconds, we may deduce that the horizontal field of view of the satellite for this band is at most a few tens of kilometres.

From observations of triggering of this band by both atmospherics and whistlers, Brice *et al.*[2] concluded that the noise was generated at the same height as the satellite. Thus the observed noise band is generated in the immediate vicinity of the satellite. Other evidence has been obtained suggesting that triggering of this band is enhanced for triggering signals propagating with large angles between the wave normal and the Earth's magnetic field. Furthermore, from examination of simultaneous very-low-frequency recordings made by the satellite and by ground-based stations, it is found that the *Alouette* hiss band is never observed on ground-based recordings.

The observation of spikes in the *Alouette* top-side sounder at the resonance frequencies for the ambient plasma[3] suggests the *Alouette* hiss band arises from a similar plasma resonance at very low frequencies. The only resonance for the frequencies of interest (5–10 kc/s) at the satellite height is the lower hybrid resonance[4] which defines a cut-off frequency for propagation transverse to the Earth's magnetic field. Other features of this resonance support the hypothesis that the lower cut-off frequency of the *Alouette* hiss band is the lower hybrid resonance for the ambient plasma.

In a subsequent paper, it will be shown that from a knowledge of the electron plasma and gyrofrequencies and the lower hybrid resonance frequency, an effective mass for the ions in the ambient plasma may be determined. Thus this hiss band may provide a powerful diagnostic tool for determining the ionic constituents of the plasma surrounding a satellite.

Assuming that the suggestion made above is correct, the observation of the *Alouette* hiss band provides, to the best of our knowledge, the first experimental confirmation of the existence of the lower hybrid resonance.

We thank Mr. John Katsufrakis of Stanford for pointing out a number of the unusual features of the *Alouette* hiss band.

Triggered Very-low-frequency Emissions

Barrington and Belrose[1] have reported that on occasion the very-low-frequency recordings from *Alouette I* satellite (altitude, 1,000 km) showed bursts of noise triggered by atmospherics which had propagated upwards to the satellite (that is, short fractional-hop whistlers) suggesting that very-low-frequency emissions were triggered at heights of less than 1,000 km.

Since some hypotheses for the generation of very-low-frequency emissions suggested generation in or near the ionospheric *F*-region[2,3], while for other hypotheses generation is more likely near the top of a magnetic field line path[4–6], it might be suggested that triggered emissions observed in *Alouette* could help to identify the mechanism responsible for generation of very-low-frequency emissions observed on ground-based recordings. However, further

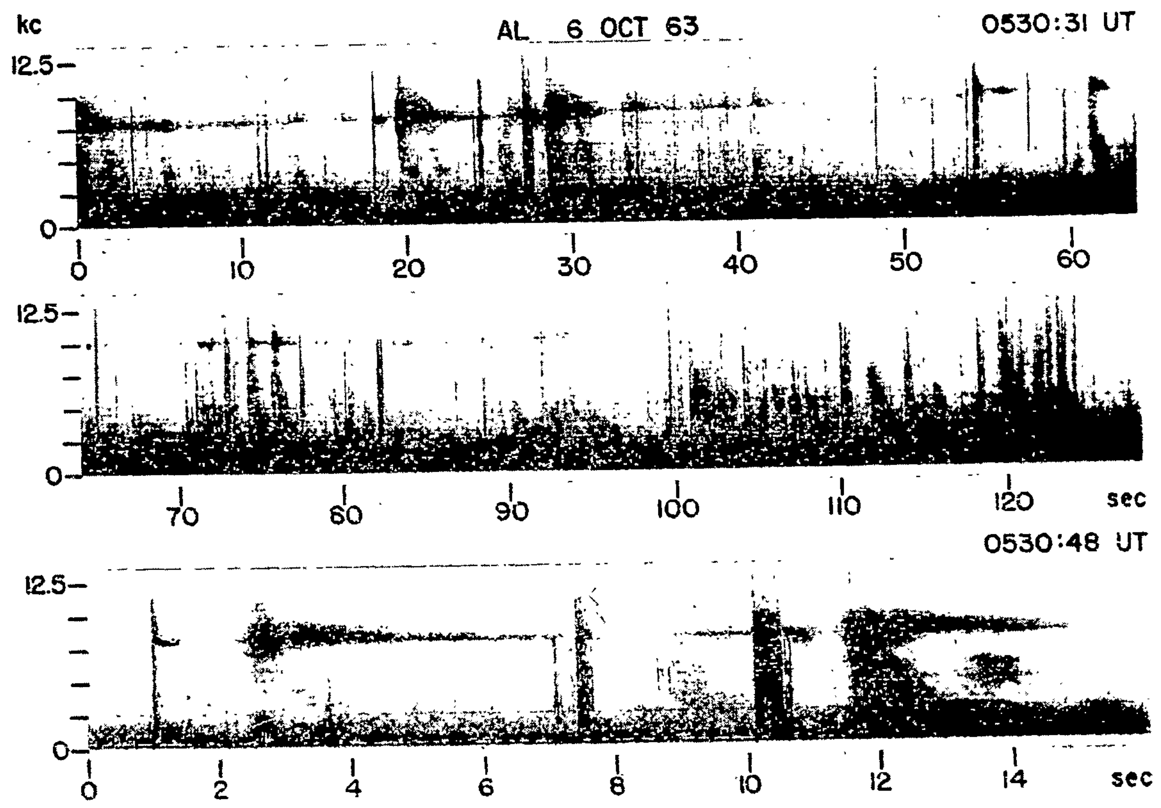

Fig. 1. Very-low-frequency spectra from *Alouette I* showing triggering by atmospherics and whistlers

investigation indicates that emissions triggered by atmospherics observed in *Alouette* are not related to very-low-frequency emissions observed on ground-based recordings[7].

Barrington and Belrose[8] reported an unusual band of noise found in *Alouette* very-low-frequency recordings. This band showed a sharp lower frequency cut-off which increased in frequency as the satellite moved to lower latitudes. This band will be tentatively referred to as the *Alouette* hiss band. Barrington and Belrose[1] noted that the frequency of emissions triggered by atmospherics varied with the satellite location in a manner similar to that of the *Alouette* hiss band already noted here. It has now been found that these phenomena are even more closely related, in that on several occasions the emissions triggered by atmospherics were, in fact, enhancements of the *Alouette* hiss band. Furthermore, this band may also be triggered by whistlers as is illustrated in Fig. 1. The lower record of Fig. 1 is a section of the upper record (17–33 sec) shown with an expanded time-scale. Fig. 1 shows spectra obtained during a north–south pass over Stanford, California, and shows the characteristic increase of frequency with decreasing latitude and the sharp lower frequency cut-off of the hiss band. The range of L values for which the noise is seen in Fig. 1 (3·15–2·59) is consistent with that reported for the *Alouette* hiss band by Barrington *et al.*[9]. The triggering by atmospherics (propagating upwards) indicates that the hiss is generated at or below the satellite (as had been suggested by Barrington and Belrose[1]) and triggering by whistlers (believed to be propagating downwards) suggests generation at or above the satellite. Thus we may deduce that the observed noise band is generated at the same height as the satellite.

Barrington *et al.*[9] reported that examination of very-low-frequency recordings obtained during a pole-to-pole pass showed evidence that the sharp lower-frequency cut-off of the *Alouette* hiss band was very closely related to the magnetic L value and that for a given value of L the lower frequency cut-off appeared to be the same in both hemispheres. Further investigation of other recordings has shown that the close conjugate relationship with L does not always hold. A possible generation mechanism which does not require magnetic conjugacy is discussed in a companion paper by Brice and Smith[7].

Alouette very-low-frequency recordings are made at Stanford from telemetry provided by the Canadian Defence Research Telecommunications Establishment in Ottawa.

The work at Stanford was sponsored by the National Aeronautics and Space Administration under grant *NsG* 174-61.

DOES QUANTUM MECHANICS EXCLUDE LIFE?

By PROF. P. T. LANDSBERG

University College, Cardiff

A LIVING object and its nutrient environment is a large quantum mechanical system. By supposing such a system to be enclosed in a container impervious to outside influences, the system may be considered to be 'closed', and quantum mechanical concepts such as Hamiltonian, wave function, and the like should be applicable to it. The question arises if, on including in such a system only a nutrient, the spontaneous generation of life is quantum mechanically likely. Secondly, is a system of nutrient together with one living organism quantum mechanically likely to produce a system containing two organisms? This is the problem of self-reproduction.

Both questions are at present beyond anything but the most speculative kind of mathematical consideration. Previous discussion of related questions by physicists exists[1-3], and the present remarks are related to the most recent of these (by Wigner[4]). A review of these questions from a biological point of view has also been published recently[5].

Wigner dealt with the second of the foregoing questions, and found that quantum mechanics leads to practically zero probability for the existence of self-reproducing states. He concluded that either present quantum mechanics cannot furnish an explanation of all that exists, or it should at least be modified to include aspects, such as consciousness, which are not needed when dealing with purely physical problems.

This conclusion makes it desirable to examine if, by broadening the main assumption and the main definition underlying Wigner's argument, it is possible to regard the empirical fact that life exists as not necessarily in contradiction with quantum mechanics. The key assumption in Wigner's paper is that the collision matrix governing the interactions in the system is a random symmetric matrix without special properties. In the present (somewhat different) approach, a weaker statistical assumption is used, and, in a special case, Wigner's conclusion is recovered. This weaker assumption does allow, however, for the possibility that the spontaneous generation of life and the existence of self-reproducing states are compatible with quantum mechanics. The key definition in Wigner's paper is that a state S is a living state if there exists a state of another ('nutrient') system such that the interaction leads with certainty to two systems in state S. If two such states are only occasionally produced (with some probability), then Wigner's argument does not hold[6]. In the present article the important problem of defining a 'living' state quantum mechanically is not faced except in a schematic manner (relations (3), below). While this is a shortcoming, it does enable one to achieve a broader understanding of the problem.

The present approach commences with the observation that the state vector of an isolated system moves with lapse of time through various regions of the appropriate energy shell in phase space. The question arises of whether there are regions in that shell which correspond to the presence of a living organism.

Immediately after death an organism can certainly be treated as a normal physical system which can in principle be fully specified. By arguing back from such a system in what is in principle a definite state, and including with it in an enlarged system, radiation and a nutrient environment, one arrives at the notion of a new physical system S. At the present state of knowledge this must be incompletely specified, but one can imagine its description and its initial state to be given in principle by a large amount of numerical information y. Whereas y is unknown, the lack of precise information about it can be made up by a statistical assumption about y. By then averaging over all y in a certain way, y disappears from the problem. There can be no doubt that this is a very superficial and rough procedure, but at present it is difficult to see how anything more definite is possible. One has, therefore, effectively replaced one system S by a class of systems. The symbol S will be retained for this class.

It is reasonable to suppose that each system (of the class of systems S arrived at in this way) has a region in its energy shell which corresponds to the presence of a living organism. In order for a class S of systems to be discussed together it is supposed here that they all have: (*a*) the same system energy; (*b*) roughly the same 'volume' of permitted states in the corresponding energy shell; (*c*) roughly the same 'volume' in that shell which corresponds to the presence of at least one living organism. In fact, these 'volumes' are replaced by numbers of distinct quantum states of the system (denoted by L_0 and L_1 in section 1).

From what has been said the problem is seen to be related to the ergodic theorem of statistical mechanics. In the more quantitative discussion which follows, results are utilized which were obtained earlier in connexion with this theorem[7]. This article contains additional mathematical information, but the results which are useful in the present context are re-derived here.

(1) Mathematical Formulation

Consider a large and isolated quantum mechanical system in some initial state at time $t = 0$. To define the system S itself and its initial state, values have to be given to a large number of variables. The symbol y will be used to denote them all. For example, the system S may consist of radiation, inorganic and organic matter. When an initial condition y is referred to, it is intended that y includes a full specification of, for example, the amount and nature of the radiation present initially. Thus, when y is given, it is supposed that the system is quantum mechanically specified. The Hilbert space of the system then contains wave-functions belonging to many different total energies. The present interest is confined to a sub-space which contains only those states which are energetically compatible with the initial condition y of the system. Such states are sometimes described as lying in an 'energy shell' in phase space. It will be denoted by the symbol Λ_0. Let its dimensionality be L_0. Each possible state of the system is then represented by a unit vector in Λ_0.

The existence of at least one living organism of any kind at time t is then expressed mathematically by the statement that the wave-function $\Psi(t)$ of the system lies wholly in the appropriate sub-space Λ_1 of Λ_0 having dimensionality L_1 say. Similarly a wave function $\Psi(t)$ lying wholly in a sub-space Λ_2, of dimensionality L_2, implies a state of the system at time t with at least two living organisms. This hierarchy may be continued until a sub-space Λ_r (corresponding to a state of at least r living organisms) is reached such that:

$$L_r \geqslant 1,\ L_{r+1} = 0 \qquad (1)$$

The isolated nutrient at time $t = 0$ can then not give rise to more than r organisms at time t. One must have clearly:

$$L_0 \geqslant L_1 \geqslant L_2 \geqslant \ldots L_{r-1} \geqslant L_r > L_{r+1} = 0 \qquad (2)$$

It is reasonable to suppose that, in fact, each L_{i+1} is very much smaller than the preceding L_i. In particular, the overwhelming majority of the states of the nutrient will correspond to no living organisms being generated:

$$L_0 \gg L_1 \gg L_2 \ldots \gg L_r \gg 1 \qquad (3)$$

Suppose the orthonormal vectors $\omega_1, \omega_2, \ldots \omega_r$ are a basis for Λ_r, and that this set is completed to yield a basis for Λ_{r-1}, then it is again completed to yield a basis for Λ_{r-2}, etc., until one has a basis for Λ_0.

The wave function of the system at time t is given by

$$\Psi(t) = A_t \Psi(0)$$

where A_t is a unitary time evolution operator. $\Psi(0)$ refers to the initial state and so depends on the values of the variables y. The projection of $\Psi(t)$ on a co-ordinate axis ω_j is:

$$a_{t,j}(y) \equiv (\Psi(t) . \omega_j) = (\Psi(0) . A_t^{+} \omega_j)\ (j = 1, 2, \ldots) \qquad (4)$$

and depends on y through $\Psi(0)$. The initial state is a vector in an L_0-dimensional space. The probability of finding the system at time t in a state with at least one living organism is:

$$u_1(t) = \sum_{j=1}^{L_1} |a_{t,j}|^2 \qquad (5)$$

and depends on y.

Consider now all initial conditions y leading to the same system energy, to L_0-values which are all of the same order of magnitude, and to L_1-values which are all of the same order of magnitude. If these initial conditions exist at all, there will be many of them, and they will lead to different interactions in the system. It is desirable to average over the conditions y as explained in the introductory remarks. One finds for the average probability of finding the system at time t in a state with at least one organism.

$$< u_1(t) > = \sum_{j=1}^{L_1} < |a_{t,j}|^2 > \qquad (6)$$

The spread of the individual values of $u_1(t)$ due to different initial conditions y is given by the second moment:

$$Z_1 \equiv \frac{<[u(t) - <u(t)>]^2>}{[<u(t)>]^2} = \frac{<u(t)^2>}{<u(t)>^2} - 1 \qquad (7)$$

Some assumptions must now be made to evaluate equations (6) and (7).

(2) Statistical Assumption

Consider equation (4). Here $\Psi(t)$ depends on the initial conditions y and is a unit vector in the L_0-dimensional space. Its components are complex, so that $\Psi(t)$ is specified by $2\,L_0$ real numbers. The simplest statistical assumption one can make about the initial conditions y is to suppose that they lead to a wave function $\Psi(t)$ such that these $2\,L_0$ numbers are normal variates which are independent (except for normalization). Viewed geometrically, this implies a probability distribution for the end point of $\Psi(t)$ over the surface of a sphere such that the probability of finding it in any area of the surface is proportional to that surface area. This distribution of $\Psi(t)$ will be called the strictly uniform distribution because it makes no *a priori* distinction between the different states of Λ_0. It leads to:

$$< |a_{t,j}|^2 > = 1/L_0,\ < |a_{t,j}|^4 > = 2/L_0(L_0 + 1) \qquad (8)$$

$$< |a_{t,i}\, a_{t,j}|^2 > = 1/L_0(L_0 + 1)\ (i \neq j)$$

There is no need here to prove equations (8), since a procedure will now be described which is more general, and yet simpler. Note that the averages (8) are independent of the co-ordinate on which $\Psi(t)$ is projected. This property will be used to define a weakly uniform distribution of $\Psi(t)$. This name is a reminder of the fact that the states of Λ_0 are no longer treated as exactly on the same footing.

It will be supposed that the distribution of permissible initial conditions y is weakly uniform so that, in generalization of equation (8):

$$< |a_{t,j}|^2 > \equiv P_1,\ < |a_{t,j}|^4 > \equiv Q_1 \qquad (9a)$$

are independent of j and the average:

$$< |a_{t,i}\, a_{t,j}|^2 > \equiv R_1\ (i \neq j) \qquad (9b)$$

is independent of i and j.

The suffix 1 for P, Q and R shows that the average is over only those initial conditions y which lead to L_0-values which are all of the same order of magnitude, and to L_1-values which are all of the same order of magnitude.

The simplest example occurs for vectors with real components in a plane ($L_0 = 2$). $\Psi(t)$ is then a unit vector in a plane and there are only two functions $a_{t,j}$ in equation (4), namely, $a_1 = \cos\alpha$, $a_2 = \sin\alpha$, where any one value of α ($0 \leqslant \alpha < 2\pi$) is the result of the initial conditions y. Suppose that the uncertain initial conditions are such that the probability of finding an angle in the range (α, $\alpha + \mathrm{d}\alpha$) is given by:

$$f(\alpha)\mathrm{d}\alpha = A \sin^b(2\alpha)\mathrm{d}\alpha$$

A is a normalizing constant. Thus for a strictly uniform distribution ($b = 0$):

$$P_1 = \tfrac{1}{2},\ Q_1 = \tfrac{3}{8},\ R_1 = \tfrac{1}{8}\ (b = 0)$$

A weakly uniform distribution is obtained, for example, if $b = 2$, when:

$$P_1 = \tfrac{1}{2},\ Q_1 = \tfrac{5}{16},\ R_1 = \tfrac{3}{16}\ (b = 2)$$

In the second case it is seen that the two states of Λ_0 are not treated as entirely on the same footing. (The equations (8) with $L_0 = 2$ do not give the foregoing result for $b = 0$. This is merely due to the fact that it is presupposed in (8) that all vectors have complex components.)

It is now easily shown by averaging:

$$\sum_{j=1}^{L_0} |a_{t,j}|^2 = \sum_{i=1}^{L_0} \sum_{j=1}^{L_0} |a_{t,i}\, a_{t,j}|^2 = 1$$

that, using equations (9):

$$P_1 = Q_1 + (L_0 - 1)R_1 = 1/L_0 \qquad (10)$$

Thus the distribution (9) has only one unidentified parameter. It is convenient to treat Q_1 as unknown, and work with:

$$X_1 \equiv L_0{}^2 Q_1 - 1 \qquad (11)$$

as a parameter. Then[7]:

$$L_0 - 1 \geqslant X_1 > 0 \tag{12}$$

Note that for a strictly uniform distribution (8) leads to:

$$X_1 = (L_0 - 1)/(L_0 + 1) \sim 1 \tag{13}$$

Using equations (9), (10), (11) in (6) and (7), one finds (see appendix):

$$< u_1(t) > \ = L_1/L_0 \tag{14}$$

$$Z_1 = \frac{L_0 - L_1}{L_0 - 1}\,\frac{X_1}{L_1} \tag{15}$$

Since $< u_1(t) >$ is independent of time, it must be regarded as the probability, averaged over the initial conditions y, of these initial conditions giving rise to at least one living organism at any subsequent time.

One finds from equations (3) and (14) that the initial conditions will on average be exceedingly unfavourable for spontaneous generation of life. But it is exeedingly unfavourable for the overwhelming majority of initial conditions y only if $Z_1 \ll 1$. For this inequality would indicate a strong clustering of the individual $u_1(t)$-values very close to the mean value (14) and this is seen to be very small. If one adopts (3) $Z_1 < X_1/L_1$. If one also uses equation (13), thus assuming a strictly uniform distribution, one does, in fact, find that spontaneous generation has always practically zero probability. There is, however, the crucial question of the size of X_1, in the case of a weakly uniform distribution of the wave function $\Psi(t)$. By equations (2) and (12) $X_1 \sim L_1$ is possible, and would lead to $Z_1 \lesssim 1$. In this event the spread of the unaveraged probability $u_1(t)$ would be sufficient to guarantee the occasional spontaneous generation of life.

(3) Self-duplication

The foregoing considerations may be extended to discuss the question of the existence of a self-reproducing unit. In the text following equation (4) one need merely make the replacements:

$$\text{suffices } 0 \longrightarrow \text{suffices } 1,\ \text{suffices } 1 \longrightarrow \text{suffices } 2 \tag{16}$$

Thus the probability of finding the system at time t in a state with at least two living organisms is:

$$u_2(t) = \sum_{j=1}^{L_2} |a_{t,j}|^2 \tag{17}$$

One now considers only those initial conditions y which, apart from having the same system energy, lead to L_1-values which are all of the same order of magnitude, and which lead also to L_2-values which are all of the same order of magnitude. The averages (9) are over the wave functions $\Psi(t)$ corresponding to these conditions y, and are now given a suffix 2. One finds instead of equations (14) and (15):

$$< u_2(t) > \ = L_2/L_1 \tag{18}$$

$$Z_2 = \frac{L_1 - L_2}{L_1 - 1}\,\frac{X_2}{L_2} \tag{19}$$

This shows again in virtue of equation (3) that the initial conditions will be exceedingly unfavourable to self-duplication. The spread of the probabilities $u_2(t)$ is determined by X_2 which is subject to the analogue of (12):

$$L_1 - 1 \geqslant X_2 > 0 \tag{20}$$

Thus if:

$$X_2 \gtrsim L_2$$

Z_2 is large enough to guarantee the occasional occurrence of initial conditions favourable to self-duplication.

If it is assumed that the distribution of $\Psi(t)$ is strictly uniform, one may use the analogue of (13)

$$X_2 = (L_1 - 1)/(L_1 + 1) \tag{21}$$

This is of order unity, so that $Z_2 \ll 1$. One must conclude that for all initial states considered, the probabilities u_2 lie very close to the exceedingly small mean value (18). Self-reproducing units must then be expected to have practically zero probability. This is essentially Wigner's conclusion which was mentioned in the introductory remarks.

(4) Conclusion

The crucial step in the argument presented here resides in the statistical assumption which has been made. While this assumption, though rough, may be justifiable in the case of equilibrium systems, it is less reasonable in the case of the non-equilibrium situations discussed here. There are, however, two reasons for using it. First, it is known[9] that in some cases non-equilibrium situations may be treated by the methods of equilibrium statistical mechanics. Secondly, some averaging process is clearly needed, and that adopted here appears to be the simplest which retains some degree of flexibility since it contains the parameter X_1. For the most sweeping averaging process $X_1 \sim 1$ (equation (13)), $X_2 \sim 1$ (equation (21)). If this is assumed, the probability of finding either spontaneous generation of life, or a self-reproducing state, appear to be practically zero. This is in agreement with Wigner's result. However, it may be that larger values of X_1 or X_2 are more appropriate. The probabilities are then more favourable and Wigner's contradiction between quantum mechanics and the existence of self-reproducing units can be avoided.

I thank Prof. E. P. Wigner and Dr. I. E. Farquhar for comments on the manuscript.

Appendix: Proof of (15)

By (5) and (9)

$$< u_1^2 > \ = \ < \sum_{j,k=1}^{L_1} |a_{tj} a_{tk}|^2 > \ = \sum_{j=1}^{L_1} < |a_{tj}|^4 > + \sum_{j \neq k}^{L_1} < |a_{tj} a_{tk}|^2 > \ = L_1 Q_1 + L_1(L_1 - 1)R_1$$

Eliminating R_1 by (10),

$$< u_1^2 > \ = \frac{L_1(L_0 - L_1)}{L_0 - 1}\,Q_1 + \frac{L_1(L_1 - 1)}{L_0(L_0 - 1)}$$

By (7),

$$Z_1 + 1 = \frac{< u_1^2 >}{< u_1 >^2} = \frac{L_0^2(L_0 - L_1)Q_1 + L_0(L_1 - 1)}{L_1(L_0 - 1)}$$

Hence one finds (15) in the form

$$Z_1 = \frac{L_0 - L_1}{L_1(L_0 - 1)}\,(L_0^2\,Q_1 - 1).$$

CHEMICAL POTENTIALS AND ELECTRICAL POTENTIALS IN BIOLOGICAL SYSTEMS

By Dr. NORMAN R. JOSEPH, Dr. MILTON B. ENGEL and Prof. HUBERT R. CATCHPOLE

University of Illinois Professional Colleges, Departments of Chemistry, Orthodontics and Pathology, Chicago

WHEN an aqueous solution of a protein or another non-dialysable electrolyte is separated by a dialysing membrane from an outer solution, there is an equilibrium between the two solutions in which the distribution of all the diffusible ions is determined by the colloidal charge[1]. The distribution ('Donnan equilibrium') is characterized by the property that the ratios of all ions of the same charge are equal in the two phases. If, for example, the ratio of sodium to potassium is 10 : 1 in the inner solution, it is the same in the outer solution, despite the fact that the inner and outer concentrations may be quite different. A system conforming to these conditions may be said to show the property of perfect or unrestricted mixing of the ions in the two phases; the distribution is perfectly non-selective. In such a system there is a membrane potential which can be calculated from any of the ion distribution ratios by means of an ideal form of the Nernst equation. When allowance is made for the ionic charge, all the ratios are constant. Therefore, there is a simple correlation between the membrane potential and the distribution ratio for any kind of diffusible ion[1]. This is not generally the case in biological structures where insoluble and immiscible phases co-exist and where the ideal equations fail to describe ionic distributions and electrical potentials. A more general treatment is required which takes account of changes in standard chemical potential of all the ions[2,3]. Ideal Donnan and Nernst relations represent a limiting case when these values approach zero.

The most general formulation of heterogeneous equilibrium was given by J. Willard Gibbs[4]. The equations apply to the thermodynamic conditions for stability of a physicochemical system consisting of n components distributed among p co-existent phases. The phases are defined in the most general sense, and may be liquid, gaseous or solids in any possible states of aggregation. In general, there can be no perfect mixing of the diffusible components in heterogeneous systems, and the phases usually differ greatly in composition except in the neighbourhood of certain critical states. It will be shown here that the distribution is determined by the changes of standard chemical potential, $\Delta\mu^0$, of all the ions between any two phases, and that these quantities also account for the deviations of electrical potential differences from the limiting form of the Nernst equation.

Distribution of ions in biological systems. In the derivation of the phase rule, Gibbs[4] showed that for any component, 1, which passes freely across a boundary between any two phases, the equilibrium condition of minimal free energy requires that the chemical potential, μ_1, be constant. If there are p such phases:

$$\mu_{1'} = \mu_{1''} \ldots. = \mu_{1^p} \tag{1}$$

Hence for each such component there are $(p - 1)$ conditions of equilibrium among the p phases. Between any two phases:

$$\Delta\mu_1 = 0 \tag{2}$$

Equations (1) and (2) are thermodynamic and are perfectly general. They do not depend on special properties of any of the phases. The chemical potential of any component is a force function which determines the stability of any distribution involving that component. The change of chemical potential, $\Delta\mu$, of any process measures the driving force and the direction of the corresponding physicochemical change. When $\Delta\mu$ for such a process is zero, the driving force is zero. When all such possible changes of chemical potential of the n components in p phases are zero, the system is in a state of minimal free energy and of maximal stability. In the case that a number of substances are constrained to cross a phase boundary in certain fixed proportions, the equilibrium condition for the two-phase distribution is:

$$a\mu_{1'} + b\mu_{2'} + c\mu_{3'} \ldots = a\mu_{1''} + b\mu_{2''} + c\mu_{3''} \ldots \tag{3}$$

where a, b and c are constants defining the proportionality factors (ref. 4, equation 78). Applied to an electrolyte such as sodium chloride, both a and b are 1. Then the equilibrium condition requires that:

$$\mu_{\mathrm{Na}'} + \mu_{\mathrm{Cl}'} = \mu_{\mathrm{Na}''} + \mu_{\mathrm{Cl}''} \tag{4}$$

and

$$\Delta\mu_{\mathrm{Na}} + \Delta\mu_{\mathrm{Cl}} = 0 \tag{5}$$

For calcium chloride, a is 1 (Ca) and b is 2 (Cl). In general, the distribution of i kinds of mobile ions would be expressed by the following conditions:

$$\frac{\Delta\mu_1}{z_1} = \frac{\Delta\mu_2}{z_2} = \frac{\Delta\mu_3}{z_3} \ldots. = \frac{\Delta\mu_i}{z_i} \tag{6}$$

where z_i is the charge of the ionic species i. It is taken as positive for cations and as negative for anions. For a two-phase system containing Na, K and Cl ions:

$$\Delta\mu_{\mathrm{Na}} = \Delta\mu_{\mathrm{K}} = -\Delta\mu_{\mathrm{Cl}} \tag{7}$$

Equations (5) and (7) state as an equilibrium condition that the tendency of sodium or potassium to pass from phase 1 to phase 2 is equal to that of chloride to pass from phase 2 to phase 1. The tendency of sodium chloride or potassium chloride to cross the phase boundary is therefore zero (equation (4)).

Equations of this form have been applied by us to the description of ionic distributions in biological systems[3]. For the distribution of sodium and potassium in normal cells and tissues the relation takes the form:

$$\Delta\mu_{\mathrm{K}^0} - \Delta\mu_{\mathrm{Na}^0} = -RT \ln \frac{r_{\mathrm{K}}}{r_{\mathrm{Na}}} \tag{8}$$

where $\Delta\mu_{\mathrm{K}^0}$ and $\Delta\mu_{\mathrm{Na}^0}$ denote the changes of standard chemical potential of potassium and sodium, and r_{K}, r_{Na} are the ion concentration ratios:

$$\frac{c_{\mathrm{K}''}}{c_{\mathrm{K}'}} \text{ and } \frac{c_{\mathrm{Na}''}}{c_{\mathrm{Na}'}}$$

The concentrations in a cellular or tissue phase are denoted as $c_{\mathrm{K}''}$ and $c_{\mathrm{Na}''}$; the concentrations in blood serum are $c_{\mathrm{K}'}$ and $c_{\mathrm{Na}'}$. In a system with perfectly non-selective distribution:

$$r_{\mathrm{K}} = r_{\mathrm{Na}}$$

and

$$\Delta\mu_{\mathrm{K}^0} = \Delta\mu_{\mathrm{Na}^0}$$

These are the conditions for the ideal Donnan distribution[1,3]. (The functions $\Delta\mu_{\mathrm{K}^0}$ and $\Delta\mu_{\mathrm{Na}^0}$ are the changes of standard chemical potential between blood serum and the given cell or tissue. According to equation (7), $\Delta\mu_{\mathrm{K}}$ and $\Delta\mu_{\mathrm{Na}}$ are non-specific for the ions. They depend only on the nature of the two phases. The specific terms of the equilibrium are $\Delta\mu_{\mathrm{Na}^0}$ and $\Delta\mu_{\mathrm{K}^0}$. They depend on the nature of the two ions and the nature of the two phases. The terms $RT \ln r_{\text{Na}}$ and $RT \ln r_{\text{K}}$, therefore, depend on the non-specific constants $\Delta\mu_{\text{Na}}$ and $\Delta\mu_{\text{K}}$ and on the two defined specific functions.)

Definition of standard state. In true homogeneous solutions, activity coefficients may be extrapolated to infinite dilutions as a state of reference. This is not possible for cells and tissues, which are more nearly like invariant heterogeneous systems in which ion concentrations cannot be varied continuously or independently of those in contiguous phases. Because biological measurements presuppose a mean state or tendency, the normal physiological resting state is chosen as the standard state and all activity coefficients are assigned the value of 1·0 (ref. 3). Standard values of $\Delta\mu_{\text{K}^0}$ and $\Delta\mu_{\text{Na}^0}$ apply to that state. All phase rule derivations assume the equilibrium condition that the free-energy change, ΔG, is zero. For cells and tissues in their most stable resting states the standard free energy of sodium–potassium distribution, $\Delta G^0{}_{(\text{K,Na})}$, may be calculated from the observed distribution ratios[3]. When defined as:

$$\Delta G^0{}_{(\text{K,Na})} = -RT \ln \frac{r_{\text{K}}}{r_{\text{Na}}} \tag{9}$$

it may be determined from the normal invariant ratios, r_{K} and r_{Na}. As calculated for a number of cells and tissues in solid or semi-solid states of aggregation, the value generally falls between $-2{\cdot}1$ and $-3{\cdot}2$ kcal (Table 1). The value $-2{\cdot}1$ kcal corresponds to an approximate equality between intracellular sodium and potassium, while the value $-3{\cdot}2$ kcal is found when the intracellular potassium exceeds the sodium by a factor of about 5. All distribution ratios are referred to the normal blood serum of the species.

Table 1. STANDARD FREE ENERGIES OF SODIUM–POTASSIUM DISTRIBUTION (values in kcal)

Cell or tissue	Species Values of ($-\Delta G^0{}_{\text{K,Na}}$) Man	Cattle	Rabbit	Rat	Mouse	Frog	Ref.
Erythrocyte	3·1	1·2	3·2	3·0	—	—	(5)
Whole brain	2·1	2·4	2·5	2·5	2·6	—	(6)

Lens	2·2	2·4–3·2	3·2	2·5	—	—	(7)
Epidermis	2·4	—	—	—	2·4	2·5	(8, 9)

* Calculated by means of equation 9 from values of r_{Na} and r_{K}. Analytical data obtained from refs. 5–9, using mean values.

In many body fluids the value of r_{K} approaches that of r_{Na}, and $\Delta G^0{}_{(\text{K,Na})}$ approaches zero[3]. This conforms to the condition for the ideal Donnan distribution, in which all the ion ratios (univalent) are equal. It is not true of coexistent phases in general, where the changes of standard chemical potential are not zero. Equations 1–9, inclusively, are more general and apply to all possible states of aggregation and to all degrees of mixing within any phase.

Normal resting potentials of cells and tissues. When electrical differences of potential are measured between an intracellular phase and the external milieu they are often found to be of a magnitude of -50 to -100 mV, with the negative sign referring to the intracellular region. When the electrical circuit is closed, chloride and other anions transport current from the external fluid into the cell, while potassium and sodium flow in the opposite direction. The free-energy change of the process is negative, and each kind of ion flows from a higher to a lower chemical potential. In a system with perfectly unrestricted mixing of the diffusible ions in each phase, $\Delta\mu^0$ is zero for all the ions. Accordingly, for any kind of anion or cation:

$$\Delta\mu_i = RT \ln \frac{c_i''}{c_i'} \tag{10}$$

The difference of electrical potential in the limiting case is expressed by the ideal form of the Nernst equation, as applied by Donnan[1]:

$$\Delta\mu_i = -96{,}500\, z_i E \text{ (joules)} \tag{11}$$

where the value of the Faraday constant is 96,500 coulombs. Also:

$$\Delta\mu_i = -23{,}060\, z_i E \text{ (calories)} \tag{12}$$

Since the ratio of $\Delta\mu_i$ to z_i is constant for all diffusible ions:

$$E_{i,\text{ideal}} = -\frac{2{\cdot}303\, RT}{96{,}500\, z_i} \log_{10} \frac{c_i''}{c_i'} \tag{13}$$

In the more general case:

$$\Delta\mu_i = \Delta\mu_{i^0} + RT \ln \frac{c_i''}{c_i'} \tag{14}$$

(The change of standard chemical potential $\Delta\mu_{i^0}$ is defined by equation (14). Its value is determined by the difference between $\Delta\mu_{i,\text{real}}$ and $\Delta\mu_{i,\text{ideal}}$. In any biological phase the absolute value of the standard chemical potential of any kind of ion is unknown and indeterminate. The measurable quantities are the real and ideal changes of chemical potential. It is usually true in thermodynamic calculations that the absolute values of the functions are unknown. For example, the standard electrode potential of sodium is defined in relation to that of hydrogen, which is assigned the value of zero volts. The measurable quantities are the changes of the functions between any two states: changes of free energy and chemical potential, for example. In cells and tissues any kind of ion occurs at different concentrations in all the phases. Each phase in the normal state is characterized by the value of μ_{i^0} for the particular kind of ion in that phase; this is a factor in the distribution. The measurable quantity is $\Delta\mu_{i^0}$ rather than μ_{i^0}.)

The electromotive force, E, is then calculated from equations 11 and 14:

$$E = -\frac{\Delta\mu_{i^0}}{96{,}500\, z_i} - \frac{2{\cdot}303\, RT}{96{,}500\, z_i} \log_{10} \frac{c_i''}{c_i'} \tag{15}$$

or

$$E_{\text{real}} = E_{i,\text{excess}} + E_{i,\text{ideal}} \tag{16}$$

Correlation of distribution ratios and electrical potentials. In the general case the observed electromotive force may be expressed as the sum of an ideal term, given by the distribution ratio of any ion, and an excess term, proportional to $\Delta\mu^0$ for that ion. The excess term may be measured as the difference between the observed electromotive force and the ideal electromotive force estimated from the distribution ratio for the given kind of ion. The change of standard chemical potential between the two phases is $\Delta\mu_{i^0}$; according to equation (15), it may be estimated from the excess electrical potential difference. Thus:

$$\Delta\mu_{i^0} = -23{,}060\, z_i E_{i,\text{excess}} \text{ (calories)} \tag{17}$$

By the use of the conversion factor, 100 mV are equivalent to 2·306 kcal. Observed resting potentials for a number of biological structures are given in Table 2. The values range from about -50 to -100 mV. In each case the values of r_{K} and r_{Na} are also given, and from

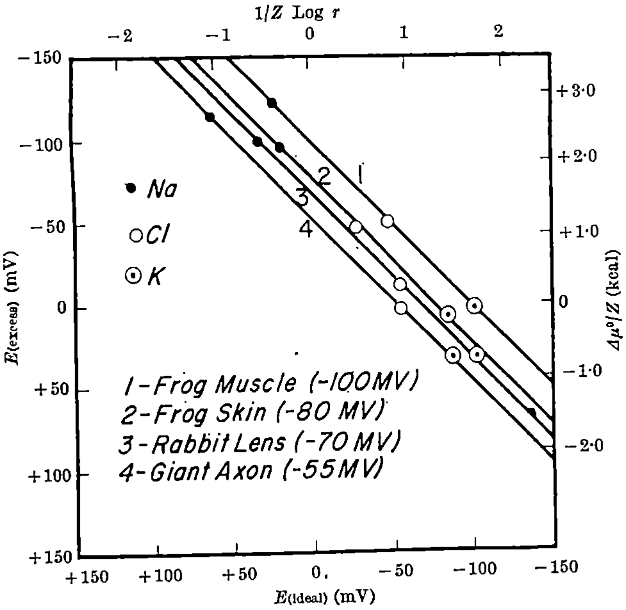

Fig. 1. Distribution of sodium, potassium and chloride ions in relation to resting electrical potentials. Family of parallel lines represents resting potentials of four different tissues. Ordinates, excess electrical potentials; excess chemical potentials. Abscissæ, ideal electrical potentials and ion distribution ratios on logarithmic scale

these the values of $E_{\mathrm{K,ideal}}$ and $E_{\mathrm{Na,ideal}}$ are estimated by means of equation (13). The excess electrical potential for each ion is estimated from equation (16); from these values, $\Delta\mu_{\mathrm{K}^0}$ and $\Delta\mu_{\mathrm{Na}^0}$ are obtained in calories (equation (17)). The values of $\Delta\mu_{\mathrm{K}^0}$ range from 0 to about −0·8 kcal (35 mV); those of $\Delta\mu_{\mathrm{Na}^0}$ are typically of the order of magnitude of 2·3 kcal (−100 mV). Table 2 also includes values of $\Delta G^0_{(\mathrm{K,Na})}$, the standard free energy of sodium and potassium distribution. These values range from −2·1 to −3·4 kcal. It is evident that the magnitudes are largely determined by the high positive values of μ_{Na^0}, the standard chemical potential of sodium.

Results are shown graphically in Fig. 1, which also includes values for chloride. The family of parallel diagonal lines represents the observed resting potentials, each of which is the sum of an ideal term (abscissa) and an excess term (ordinate). The ion concentration ratios are expressed by a logarithmic scale parallel to the abscissa. The changes of standard chemical potential of each kind of ion are shown on the vertical scale at the right. Potassium and chloride ions show the smallest deviations from the ideal Nernst equation and the smallest changes of standard chemical potential. Fig. 1 illustrates the relation between ion distributions, excess electrical potentials and changes of standard chemical potential for each kind of ion.

Distribution of ions and electrical potentials at equilibrium is based not on equality of concentration ratios but on equality of chemical potentials. Depending on the nature of the phases, biological systems may show changes of standard chemical potential which are close to zero, in which case they would conform to the Donnan distribution and to the ideal Nernst equation. Examples of this are the blood serum and contiguous body fluids. On the other hand, cells and tissues are highly ordered structures, made up of insoluble and soluble charged macromolecular components, where the criterion for equilibrium is that the changes of chemical potential be constant for all ions of the same charge. Then both distribution ratios and resting electrical potentials are determined by the standard chemical potential of each kind of ion in each of the phases.

EARLY FOLDS AND THE *a*-LINEATION AT TINTAGEL, CORNWALL

By Dr. W. R. DEARMAN

Department of Geology, University of Newcastle upon Tyne

AND

Dr. E. C. FRESHNEY and M. C. McKEOWN

Geological Survey and Museum, South Kensington, London, S.W.7

The small-scale tectonic structures imprinted on the Upper Devonian slates and volcanic rocks of Tintagel, on the north coast of Cornwall, were used by Dr. Gilbert Wilson[1] to demonstrate that a general shearing movement had taken place throughout groups of beds and on separating thrust planes. Upper beds had moved north-north-westerly relative to those below. Earlier, Henry Dewey[2] had shown that the structure of the area was apparently a simple, conformable pile of gently dipping strata sliced locally by flat-lying thrusts. The later work confirmed this view but corrected Dewey's interpretation that thrust-bounded slices had ridden up the thrust planes in a general easterly direction, and thus rehabilitated the area into the conventional Hercynian tectonic pattern of Cornwall.

In accepting the general congruity of the structures, the observed linear structural elements were grouped by Dr. Wilson into those indicative of the *b*-tectonic direction and others at right-angles, which had perforce to be labelled as structures parallel to the direction of tectonic transport, namely, the *a*-tectonic direction. The *b*-lineations were the axes of drag folds, the intersection of fracture-cleavage with bedding, and the long axes of boudins; *a*-lineations included certain bedding plane lineations, elongated mineral spots, and the long axes of stretched pillows in the interbedded lavas.

One anomalous feature remained, however, and that was the general absence of folds other than drag folds in the tectonic pattern of the area. Indeed, De Sitter[3], in discussing the boudins which are so well displayed at

Tintagel, remarked that the parallelism of nearly horizontal bedding and slaty-cleavage implied the presence of recumbent folds.

Meanwhile, investigations in neighbouring areas in Cornwall and Devon[4] have revealed a consistent pattern of superimposed structures in Devonian and lowest Carboniferous slates. Particularly relevant to the present discussion are the minor structures at Lydford in Devon (inset map, Fig. 1) on the north-west border of Dartmoor. Here the River Lyd Slates-with-lenticles Group is the lateral equivalent of at least part of the Tintagel succession[5-7]. Early folds in the slates are very tight to isoclinal with an axial-plane slaty-cleavage and often a well-marked bedding-cleavage lineation. The axial trend of these early, or F_1, folds varies from south-west to north-west in areas where the cleavage is flat-lying. F_1 folds are folded by later, more open, F_2 folds with a gentle north-easterly plunge, an approximately axial plane strain-slip cleavage, and a strong lineation resulting from the intersection of bedding or slaty-cleavage and the strain-slip cleavage. These F_2 folds are overturned to the north.

Such rectangular combinations of structures, here and at other localities in Cornwall, are strong evidence for assuming that similar structures occur at Tintagel (Fig. 1). In considering this possibility, it was thought that the recorded presence of more gritty quartzitic bands in the black carbonaceous slates comprising the Barras Nose Beds[1] would serve to make F_1 folds, if present, easily visible and would at least provide an obvious bedding-slaty-cleavage lineation. The initial enquiry was therefore concentrated on Barras Nose (Grid ref. *SX* 05358944). Recumbent, very tight folds with axial-plane slaty cleavage (S_1) (Fig. 2) and gentle north-north-westerly plunge of axes occur on both sides of the headland on easily accessible ledges. The folds have limbs of unequal length, the short limbs being about 1 ft. long, while the others exceed 5 ft. Cross-lamination in the quartzitic bands shows that the short limbs are inverted and the early folds thus face west-south-west on the axial plane cleavage. Later F_2 folds (the local drags in *b*) deform the S_1 cleavage and have associated with them an axial-plane strain-slip cleavage (S_2); the latter cleavage gives rise to a second lineation trending west to west-south-west on the S_1 slaty cleavage.

Another locality investigated was the Lanterdan Quarry (Grid ref. *SX* 05108709) (Fig. 1) in the cliffs above Hole Beach, Trebarwith Strand. Greyish green slates, with thin calcareous lenticles and 2-in. thick beds of crinoidal limestone, are exposed in many easily accessible quarry faces. A small quarry (Grid. ref. *SX* 05138706) on the landward side of the cliff-top path above the main quarry provided an example of a complete fold hinge (F_1) picked out by a thin irregular band of friable weathered lime-

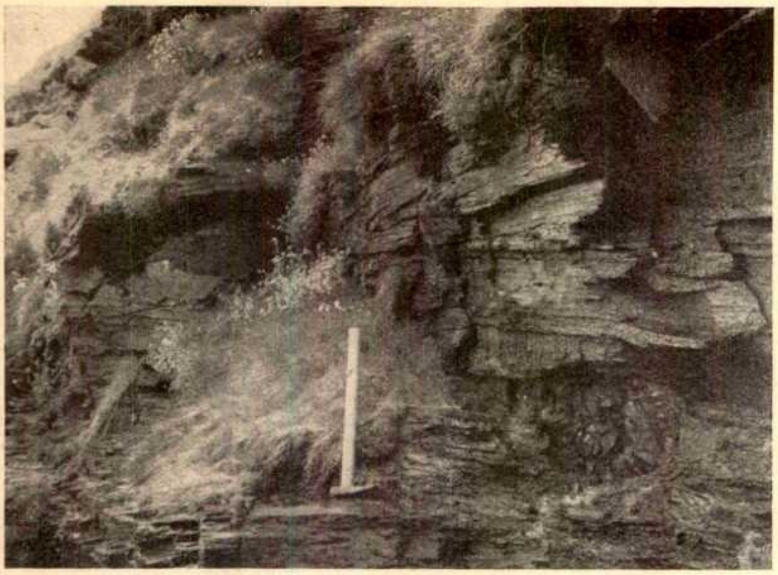

Fig. 2. Recumbent F_1 folds at Barras Nose, Tintagel

stone. The fold axis plunges gently to the north-north-west. Other F_1 folds were seen within the main Lanterdan Quarry, and wherever there are lenticles it is possible to demonstrate that the lineation on the slaty cleavage is parallel to the intersection of bedding with cleavage. Moreover, the flattened chloritic impressions of *Spirifer verneuili*, so abundant at certain levels in this quarry, are stretched out in the same direction and are affected by the later strain-slip cleavage lineation.

Other F_1 folds, with axes plunging to west-north-west and east-south-east, that is, at 60° to the north-north-west trend described, are seen at Lambshouse Quarry (Fig. 1: Grid ref. *SX* 04698795) and in the surrounding cliff faces. Northward-directed lineations are rare at this locality and may be attributed to F_2 movements.

It therefore appears that the accepted *a*-lineation at Tintagel is a *b*-lineation related to an earlier phase of recumbent isoclinal folding. Stretch structures and north-north-west directed lineations are clearly products of the first, F_1, phase of folding; the drag-folds, boudins and strain-slip lineations belong to a second, F_2, phase of folding. The dominance of north-north-west lineations implies a constant orientation of F_1 folds over most of the area from Trebarwith to Boscastle with the early folds facing west-south-west. This orientation, and the facing direction, must eventually be reconciled with the continuity of the outcrop of these strata from the coast at Boscastle to the western margin of Dartmoor, and perhaps even as far east as Okehampton.

We thank the Director of the Geological Survey for permission to publish these results. The work of one of us (W. R. D.) was supported by a grant from the Department of Scientific and Industrial Research.

1-^{14}C-GLUCOSE UTILIZATION OF INTACT NUCLEATED RED BLOOD CELLS OF SELECTED SPECIES

By MAJOR CHARLES E. SHIELDS*, YAYE F. HERMAN and MAJOR ROBERT H. HERMAN†

Department of Veterinary Microbiology, Division of Veterinary Medicine, Walter Reed Army Institute of Research, Washington 12, D.C.

INTACT normal human red blood cells metabolize 1-^{14}C-glucose via the pentose phosphate pathway (hexomonophosphate shunt) to produce $^{14}CO_2$, and this production can be stimulated by pyridine nucleotides, especially triphosphopyridine nucleotide (TPN)[1]. Since human red blood cells are non-nucleated, they are incapable of protein synthesis according to present theory. This raised the question as to whether nucleated red blood cells, presumably capable of protein synthesis, would utilize 1-^{14}C-glucose similarly to human red blood cells via the pentose phosphate pathway. We wondered whether nucleated red blood cells would metabolize 1-^{14}C-glucose more actively than non-nucleated red blood cells. Therefore the 1-^{14}C-glucose utilization of nucleated red blood cells of selected species was investigated. In particular, we examined the nucleated red blood cells of chickens (*Gallus gallus*), geese (*Anser domesticus*), ducks (*Anas boscas*), and frogs (*Rana pipiens*). Intact red blood cells were examined in order to approximate more closely their usual physiological state. In addition, total hæmolysates were also examined. Red blood cells of normal human subjects were used as controls.

Blood was obtained by venipuncture from man and by cardiac puncture from birds and frogs. The $^{14}CO_2$ production from 1-^{14}C-glucose was measured as previously described[1]. Each flask contained approximately 22,200 d.p.m. of 1-^{14}C-glucose (specific activity 1·79 mc./mmole). Avian and frog red blood cells were centrifuged at 1,800 r.p.m. Washed packed red blood cells from each individual animal or pool of blood from several animals were incubated in duplicate flasks using 0·2 ml. of cells in a total volume of 2·5 ml. with and without TPN at a concentration of 2 mM. Total hæmolysates were prepared by substituting water for the Krebs–Ringer phosphate buffer used as the incubation medium. Blood samples from each of five geese and four ducks were used, while pools of blood from 12 chickens and 23 frogs were used to constitute five separate samples of blood from these latter species. Incubation conditions were as previously described[1]. Values were expressed as the percentage of initial radioactivity counted as $^{14}CO_2$.

The results are given in Table 1. It can be seen that the intact red blood cells from man and the frog were stimulated significantly by 2 mM TPN, whereas no such stimulation occurred for the chickens, geese and ducks. When the data from each species were compared with the corresponding data for man, it was found that the avian and frog red blood cells differed significantly from the red blood cells of man. This comparison is presented in Table 2. Surprisingly, the intact avian red blood cells produced very little $^{14}CO_2$ from 1-^{14}C-glucose and the addition of TPN produced only a slight increase, if any. The frog red blood cells were intermediate between human and avian red blood cells in the amount of $^{14}CO_2$ produced and were significantly stimulated by TPN, but to a degree less than the human red blood cells.

Table 1. $^{14}CO_2$ PRODUCTION FROM 1-^{14}C-GLUCOSE BY INTACT RED BLOOD CELLS OF VARIOUS SPECIES WITH AND WITHOUT TPN

The data are given as mean values expressed as the per cent of initial radioactivity recovered as $^{14}CO_2$. Values in parentheses give the range. Statistical comparison was made using Student's t test for paired data (ref. 2)

Species	No. of subjects	Additions		Statistical comparison	
		None	TPN	t	P
Man	5	11·3 (4·6–22·6)	21·8 (11·7–41·7)	4·60	0·01
Chicken	12 animals to give 5 pools of cells	0·6 (0·1–1·2)	0·7 (0·1–1·3)	1·83	> 0·05 (n.s.)
Goose	5	0·1 (0·02–0·4)	0·7 (0·2–1·3)	2·45	> 0·05 (n.s.)
Duck	4	1·1 (0·2–2·6)	2·0 (0·3–3·7)	1·64	> 0·05 (n.s.)
Frog	23 animals to give 5 pools of cells	2·2 (1·5–3·0)	3·1 (2·3–4·6)	4·66	0·01

Table 2. Statistical comparison between intact nucleated red blood cells (RBC) of selected species and intact human red blood cells in $^{14}CO_2$ production from 1-^{14}C-glucose with and without TPN, using Student's t test for unpaired data (ref. 2)

Species RBC	No TPN		Added TPN	
	t	P	t	P
Chicken	3·12	0·02	3·74	0·008
Goose	3·18	0·02	3·75	0·008
Duck	2·94	0·015	3·48	0·01
Frog	2·64	0·04	3·31	0·01

Since the intact red blood cells produced much less CO_2 than was anticipated, total hæmolysates were examined to help determine the reason for this decreased output. Table 3 gives the results for various chicken and goose red blood cells. The chicken red blood cell total hæmolysates showed much greater production of carbon dioxide than the corresponding intact red cell preparation. The goose red blood cell total hæmolysate also produced more carbon dioxide than its intact cells but not so much as the chicken hæmolysates. TPN was greatly stimulatory in both hæmolysates.

Thus, the intact nucleated erythrocytes were far less active with regard to production of carbon dioxide from 1-^{14}C-glucose, contrary to our expectation. Several possibilities exist to account for the low production of carbon dioxide. $^{14}CO_2$ is produced from 1-^{14}C-glucose via the pentose phosphate pathway and the Krebs's tricarboxylic acid cycle (TCA cycle). Carbon dioxide would not be produced if these pathways were not present. Certainly the pentose phosphate pathway enzymes, glucose-6-phosphate dehydrogenase (G-6-PD) and 6-phosphogluconic acid dehydrogenase (6-PGAD), exist in avian red cells. Salvidio *et al.*[3] measured these in pigeon red blood cells. We have also measured these enzymes in chicken red blood cells by the method of Kornberg and Horecker[4] and found these values: G-6-PD, 15,330 units; 6-PGAD, 1,330 units (1 unit is the change of optical density of 0·001 at 340 mμ/g hæmoglobin at room temperature using a 1-cm light path). Furthermore, carbon dioxide production in the total hæmolysates was appreciable and was stimulated by TPN, which is good evidence for the presence of an active pentose phosphate pathway.

Table 3. THE $^{14}CO_2$ PRODUCTION OF INTACT RED BLOOD CELLS AND TOTAL HÆMOLYSATES FROM CHICKENS AND GEESE

The data are expressed as in Table 1

Species	No. of animals	Intact cells		Total hæmolysate	
		No additions	TPN	No additions	TPN
Chicken	Pool of 3	0·2	0·4	15·2	40·5
Chicken	Pool of 5	0·2	0·5	19·2	32·0
Goose	1	< 0·1	0·2	0·9	39·5
Goose	1	0·4	0·7	3·9	51·3
Goose	1	< 0·1	0·6	1·3	39·5
Goose	1	0·1	0·3	3·2	37·2

Dajani and Orten[5] have shown that labelled acetate is incorporated into the TCA cycle intermediates in chicken red blood cells, from which it was concluded that an active TCA cycle exists in chicken red blood cells. Thus, the presence of the pentose phosphate pathway and a presumably functional TCA cycle would be expected, if anything, to lead to greater production of carbon dioxide than in human red blood cells where a TCA cycle is lacking. Therefore, the low production of carbon dioxide by intact chicken red blood cannot be due to an absence of these pathways.

Since chicken red blood cells can utilize exogenous glucose via the pentose phosphate pathway in total hæmolysates but only to a very limited extent in the intact cell, there is the implication that there is some sort of impairment of glucose movement into the intact chicken red blood cell. The results are less striking in the goose red blood cell, though the hæmolysates still produced more carbon dioxide than the corresponding intact red blood cells.

ELECTRONIC EFFECTS AND L-AMINO-ACID OXIDASE SPECIFICITY

By DR G. K. RADDA

Department of Biochemistry, University of Oxford

QUANTITATIVE investigations of substituent effects on organic reactivities yielded linear free-energy relationships[1] which not only emphasized regularities in reactivities but also brought to attention detailed aspects of mechanisms when the linear Hammett equation was not strictly followed[2,3]. Little is known, however, about the importance of electronic effects in determining enzymatic reactivities[4,5]. The present article, as part of our work on the mechanism of reactions involving flavins and flavoproteins[6,7], deals with an investigation of substituent effects on the oxidation rates of amino-acids catalysed by L-amino-acid oxidase (LAO) found in snake venoms.

The enzyme purified from the venom of the Malayan pit-viper (*Agkistrodon rhodastoma*), not previously described, was compared with that obtained from *Crotalus adamanteus* (Sigma, Type IV)[8]. The former enzyme is very similar in physical and spectral properties to those obtained from other venoms. It has a sedimentation coefficient of 6·3 S at 0·1 per cent protein concentration, maximum absorption at 280, 390 and 460 mμ with a ratio of absorbancy 280/460 = 9·3. The method of purification and other physical properties of the enzyme will be described elsewhere.

The substrates examined were α-amino phenylacetic acid (phenylglycine) and its derivatives substituted in the aromatic nucleus. This choice was governed by the consideration that substituents should have a more significant effect when the reaction centre is conjugated with the aromatic ring[2,3]. The rates of oxidation—measured by manometric methods—catalysed by the two oxidases under identical conditions are shown in Table 1. They were calculated from the linear part of the rate curves during the first 10 per cent reaction. In the reactions when oxygen uptake was observed the products were shown to be ketones (in the presence of catalase).

Table 1. RATES OF OXIDATIONS OF AROMATIC AMINO-ACIDS BY L-AMINO-ACID OXIDASE

Substrate	Rate μl. O_2/min/mg enzyme from *Agk. rh.*	Rate μl. O_2/min/mg enzyme from *Crot. ad.*
DL-Phenylglycine	1·71	1·7
D-Phenylglycine	0	—
DL-*p*-Methyl-phenylglycine	1·46	~2·0
DL-*p*-Methoxy-phenylglycine	0·86	0·83
DL-*m*-Amino-phenylglycine	1·43	1·53
DL-*p*-Fluoro-phenylglycine	4·48	4·3
DL-*p*-Chloro-phenylglycine	5·56	5·65
DL-*m*-Fluoro-phenylglycine	0·27	~0·5
DL-*m*-Chloro-phenylglycine	0·31	~0·5
DL-*m*-Nitro-phenylglycine	0·05	v. slow
DL-*o*-Fluoro-phenylglycine	0·15	0·3
DL-*o*-Chloro-phenylglycine	0·1	—

Solutions contained: 1 mg enzyme, 30 μmoles substrate in 3 ml. buffer (0·2 M *tris*, *p*H 7·2). Rates were measured at 38° C with air in the gas phase.

The rates of oxidation of some natural amino-acids under identical conditions were also measured using LAO of *Agkistrodon rhodastoma* venom (Table 2). Taking the rate of oxidation of L-leucine as 100, the specificity of this enzyme can be compared with that obtained from *Crotalus adamanteus*[9].

Table 2. RATES OF OXIDATION OF NATURAL AMINO-ACIDS CATALYSED BY LAO from *Agkistrodon rhodastoma* VENOM

Substrate	Rates μl. O_2/min/mg enzyme	Rates rel. to leucine	Rates rel. to leucine with LAO of *Crot. ad.**
L-Leucine	24·4	100	100
DL-Leucine	25·2	103	—
DL-Tyrosine	14·2	58	82
L-Tryptophan	19·4	79	88
DL-Phenylalanine	21·2	87	82
DL-Alanine	1·2	5	0·4

Solutions as in Table 1 except that 15 μmoles of substrate were used with pure optical isomers.

* Data from ref. 9.

It is clear that the properties of the two enzymes are very similar, if not identical. The fact that phenylglycine and its derivatives are oxidized supports the hypothesis that the reaction proceeds via the α-imino-acid rather than through an αβ-unsaturated compound[10]. The mechanism of oxidation, then, probably involves the loss of the α-hydrogen (either as a hydrogen atom or as a hydride ion) to the flavin and of a proton to the solvent. This is followed by the hydrolysis of the α-imino-acid and the dissociation of the substrate from the enzyme. If the loss of the α-hydrogen is the rate-limiting step, one would expect electron-donating substituents (for example, *p*-OMe, *p*-Me, *m*-NH_2) to accelerate the reaction, and electron-withdrawing groups (for example, F- and Cl-) to retard it. The rates are affected in the opposite direction by the groups examined, with the exception of the three most strongly withdrawing meta-substituents. More significantly, when Hammett σ-values are plotted against log k/k_0 (where k_0 = rate of oxidation of unsubstituted compound; k is that of the substituted compound), a reasonably good linear correlation is obtained for the first six substituents with a ρ-value of 1·8. The three most electron-withdrawing substituents (*m*-Cl, *m*-F, *m*-NO_2), on the other hand, fall on a line with a negative slope. (The exact slope of this line is subject to large errors because of the inaccuracies in following the rates of very slow reactions.) These observations suggest that the rate-determining step is normally not the loss of the α-hydrogen but one of the two subsequent processes. The fact that tyrosine reacts slower than phenylalanine is consistent with this. In cases when the substituent would slow down the first step considerably (that is, groups with large positive σ-values) the loss of the α-hydrogen may become rate limiting, hence the anomaly in the Hammett plot. Similar breaks in Hammett plots have been reported for two other enzymatic reactions[4,5], with the difference that the change-over occurred at the unsubstituted compound.

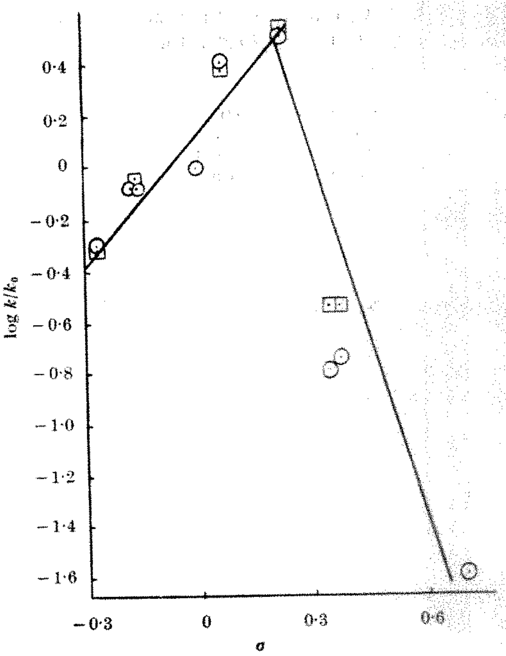

Fig. 1. Hammett plot for rates of oxidation of aromatic amino-acids. ○, by LAO from *Agkistrodon rhodastoma*; □, by LAO from *Crotalus adamanteus*

The importance of steric factors and the 'goodness of fit' of the substrate on the enzyme surface cannot, of course, be overlooked. Unfavourable steric effects may be responsible for the very low rates of oxidation of the two ortho-substituted phenylglycines. They may also effect to some extent the oxidations of the meta-substituted compounds and therefore cause the break in the Hammett plot. If this is the case, however, it is difficult to reconcile the fact that the *m*-fluoro substituent has an equal effect to the *m*-chloro group, or that the *m*-amino group has such a weak effect, for the steric requirements of these groups are considerably different, the amino group being the largest. For this reason the first interpretation for the unusual Hammett plot seems more plausible.

In considering the susceptibility of the reaction to electronic variations (this is measured by the ρ-value) it is tempting to draw comparisons with non-enzymatic reactions. The ρ-value of 1·8 is close to those observed for base-catalysed hydrolyses of esters of benzoic acid derivatives[1]. On the other hand, it is considerably larger than values for reactions or acidities involving phenylacetic acid derivatives[2]. It is therefore a reasonable working-hypothesis that the rate-determining step of the enzymatic reaction is the hydrolysis of the α-imino-acid (which is similar in mechanism to the base-catalysed hydrolysis of ethylbenzoate) rather than the dissociation of the product from the enzyme, which is likely to involve the carboxyl group insulated from the aromatic nucleus by an intervening carbon atom, as in phenylacetic acid.

I thank Dr. M. P. Esnouf for his help in the preparation of LAO, and Mr. J. H. C. Nayler for samples of most of the unnatural amino-acids.

EFFECTS OF LUMBAR SYMPATHECTOMY ON THE UTERINE UPTAKE OF CATECHOLAMINES

By Dr. JOSEF E. FISCHER, Dr. IRWIN J. KOPIN and Dr. RICHARD J. WURTMAN

Laboratory of Clinical Science, National Institute of Mental Health, National Institutes of Health,
Bethesda, Maryland

TRITIATED *nor*epinephrine (NE-^{3}H) is actively taken up from the circulation and bound in sympathetic nerve endings in many tissues, including heart, muscle and salivary gland[1]. Electron microscopic examinations have shown that the tritiated catecholamine is stored in dense-core vesicles[2]. When heart[3] or salivary gland[4] are subjected to chronic sympathetic denervation, their capacities to take up circulating tritiated catecholamine are markedly reduced.

The catecholamine stores of rat uterus differ from those of most other tissues in that the capacity of the uterus to bind circulating epinephrine is endocrine-sensitive, rising four-fold between diœstrus and œstrus[5]. In uterine homogenates, tritiated epinephrine is present largely in the 'supernatant' and not the 'microsomal' fraction[7] as in other tissues[3]. The uptake of catecholamines in the uterus is not blocked by pre-treatment with cocaine, and their release is only slightly enhanced by tyramine[7]. On the basis of these observations it has been suggested that a major fraction of the uterine catecholamines may be present in a non-neuronal store[7].

In order to obtain further information about the cellular locus of uterine epinephrine and *nor*epinephrine, estimates were made of the ability of this organ to take up and retain circulating tritiated catecholamines several weeks after bilateral lumbar sympathectomy. The effects of denervation on catecholamine uptake of gastrocnemius muscle were also determined, since this muscle is also innervated by the lumbar sympathetic chain.

Catecholamines are cleared rapidly from the circulation; thus one of the determinants of the amount of administered neurohumours bound in an organ is the proportion of cardiac output it received[8]. Sympathetic denervation could affect regional perfusion, thereby changing the proportion of tritiated catecholamine which is made available to a given organ. The fractions of the cardiac output delivered to the uterus and gastrocnemius muscle were therefore measured in denervated and sham-operated animals[9].

Female Sprague–Dawley rats weighing 170–200 g were anæsthetized with ether, and both lumbar and sympathetic chains were removed from the level of the left renal artery to below the bifurcation of the aorta. All visible ramicommunicans were extirpated and the sympathetic nerves were stripped off the iliac arteries as well. It was believed that most or all of the hypogastric plexus was destroyed. Sham-operated rats served as controls.

Two weeks after operation, each animal received 30 μc. of *d,l*-*nor*epinephrine-7-^{3}H (6·0 mc./μmole, New England Nuclear Corp., Boston, Mass.) or 30 μc. of *d,l*-epinephrine-7-^{3}H (5·0 mc./μmole) intravenously. One hour later, 1 μc. (0·2 ml. final dilution) of potassium-42 as potassium-chloride (4 m.equiv./l.) was injected intravenously. Animals were killed by decapitation 20 sec later. Uterus and gastrocnemius were rapidly removed, weighed and assayed for potassium-42 in a γ well counter. A potassium-42 standard, representing 1 per cent of the injected dose, was assayed periodically to correct for potassium-42 decay. It was assumed that uptake of potassium-42 was proportional to the percentage of cardiac output received[9]. Tissues were then homogenized in cold 0·4 N perchloric acid and the radioactive catecholamines assayed as previously described[1].

Following lumbar sympathectomy, the gastrocnemius muscles took up considerably less tritiated-epinephrine and tritiated-*nor*epinephrine (Table 1), even though they received a somewhat larger share of the cardiac output (Table 2). Denervation increased the blood flow to the uterus as well (Table 2), but uterine uptake of tritiated *nor*epinephrine and tritiated epinephrine was not changed (Table 1).

Table 1. Fractional Blood Flow to Uterus and Gastrocnemius Muscle in Bilaterally Lumbar Sympathectomized and Sham-operated Animals

Results are expressed as per cent cardiac output/g ± *S.E.M.* for groups of 12 animals

	Uterus	Muscle
Sham-operated	1·82 ± 0·16	0·213 ± 0·014
Lumbar sympathectomized	2·46 ± 0·14*	0·258 ± 0·023

*$P < 0·01$.

Table 2. Effect of Bilateral Lumbar Sympathectomy on Uptake of Tritiated *nor*epinephrine and Tritiated Epinephrine in Uterus and Gastrocnemius Muscle

Results are expressed as mμc. of tritiated catecholamine per gram of tissue ± *S.E.M.* Each figure represents the mean for 12 animals

	Tritiated *nor*epinephrine	
	Uterus	Muscle
Sham-operated	4·69 ± 0·39	9·16 ± 0·62
Lumbar sympathectomized	4·83 ± 0·35	4·50 ± 0·14*
	Tritiated epinephrine	
Sham-operated	3·45 ± 0·30	6·38 ± 0·33
Lumbar sympathectomized	4·14 ± 0·73	3·46 ± 0·11*

*$P < 0·001$.

It has been shown that circulating tritiated catecholamines are bound by sympathetic nerves in many tissues[3], and that the capacity of these tissues to bind epinephrine and *nor*epinephrine is diminished following sympathetic denervations[3,4,10]. Unimpaired uptake following chronic sympathetic denervation would suggest either a failure in postganglionic denervation or the presence of an extraneuronal catecholamine store.

The uterus of the rat receives its sympathetic nerve supply from the lumbar sympathetic chain via the hypogastric plexus[11]. It is not known what fraction of the uterine sympathetic nerves have their cell bodies within neither the ganglia of the lumbar sympathetic trunks nor the hypogastric plexus. Some sympathetic ganglion cells may be present on the surface of the uterus, or within the uterine muscle; such has been shown to be the case in the vas deferens[12]. Hence the 'denervation' procedure used here may represent a total decentralization of the uterus but only a partial postganglionic sympathetic denervation. Presumably a major portion of the uterine postganglionic sympathetic nerves was destroyed, yet, unlike the gastrocnemius muscle, there was no decrease at all in the catecholamine-binding capacity of the uterus. It thus appears that either the usual correspondence between sympathetic innervation and catecholamine storage does not hold for the uterus, or that most postganglionic fibres to the uterus arise distal to the areas of dissection.

The 'extraneuronal' pool of *nor*epinephrine present in denervated salivary gland is reserpine resistant[4]. Reserpine, however, depletes the uterus of *nor*epinephrine[7]. Since reserpine blocks the uptake of tritiated *nor*epinephrine to sympathetic ganglia[13], the data are consistent with the hypothesis that a fraction of uterine catecholamines is present in ganglion cells in the uterus.

If the catecholamines in the uterus are 'extraneuronal' their binding site is pharmacologically different from that described in all other organs examined thus far. The choice of the correct alternative requires the accumulation of more information on the anatomy of the uterine sympathetic nerves.

SPECIFICITIES OF SEVERAL ACID PHOSPHATASES FROM PLANT SOURCES

By TOMOYOSHI IKAWA, PROF. KAZUTOSI NISIZAWA and PROF. TOMOO MIWA

Botanical Institute, Tokyo Kyoiku University, Otsuka, Tokyo

UNLIKE the phosphatases of animal origin[1], those from plant sources have so far been examined only to a limited extent and some of the reported results are incompatible with each other. The possible identity of phosphomonoesterase and pyrophosphatase in higher plants has been suggested by some workers[2,3], whereas the independent nature of these enzymes in yeast has been claimed by others[4,5]. On the other hand, the relation of these phosphatases to phytase, which has often been believed to be a distinct enzyme[3,6], has recently been criticized[7]. Meanwhile, the presence of isodynamic enzymes or isozymes was reported for the plant phosphatases[8,9].

In the present work the crude preparations of phosphomonoesterase from the ears of rice plant, mycelia of *Aspergillus niger* and kernels of apricot were fractionated and the substrate specificity of each fraction was examined. As a result of these investigations, the existence in these plant materials of isodynamic phosphatases was confirmed and their specificities were investigated.

The precipitate (125 mg protein), obtained from an aqueous extract of unripened rice-ear with ammonium sulphate between 25 and 70 per cent saturation, was dissolved in 0·01 M *tris*-buffer of *p*H 7·6, applied on a DEAE-cellulose column (1·5 × 14 cm with 6 g of DEAE cellulose) and eluted with gradient concentrations of 0–0·42 M sodium chloride solution (180 ml.) at a rate of 8 ml. effluent/h.

Dried mycelia of *A. niger* were extracted with 0·2 per cent orthophosphate. The precipitate (120 mg protein) formed with 70 per cent acetone was dissolved in *tris*-buffer of *p*H 7·6 and subjected to DEAE-cellulose column chromatography (1·0 × 12 cm with 3·5 g DEAE-cellulose) in a similar way to the foregoing with a flow rate of 2·5 ml./h.

An enzyme extract (42 mg protein), obtained from the acetone powder of apricot kernels, was fractionated by DEAE-cellulose column chromatography under the same conditions as with *A. niger*, except that the flow rate was 4 ml./h.

The phosphatase preparation from rice-ears was resolved into three fractions (I–III) as shown in Fig. 1. Phosphatase III (Phos III) showed on zone electrophoresis a single component which was active for all substrates tested. The electrophoretic conditions were: $\mu = 0{\cdot}05$, 250 V, 16–18 m.amp, 26 h. The other two fractions (phosphatases I and II) were not examined electrophoretically. However, on heating at 50° C for 15 and 30 min, phosphatase I uniformly lost its activities by about 58 per cent and 65 per cent, respectively, towards various substrates, and phosphatase II also uniformly lost about 30 per cent and 35 per cent of its activities, respectively, under the same conditions. This finding may suggest the homogeneous nature of the two fractions. The activities of these fractions towards a variety of substrates are summarized in Table 1. In contrast to phosphatase II, the specificities of phosphatases I and III appear to be broad, as revealed by their activities on pyrophosphate and phytin besides phosphomonoesters. Particularly high activities of phosphatases II and III towards arylphosphate are to be noticed.

The maximal activity of phosphatase I was found at *p*H 4·5 for *p*-nitrophenyl phosphate, β-D-glucose-1-phosphate, pyrophosphate and phytin, and that of phosphatases II and III at *p*H 5·0 for respective substrates. Mg^{++} and Mn^{++} in 10^{-3} M showed no effect. However, the inhibition by F^- (2×10^{-2} M), Mo^{++} (2×10^{-3} M) and Cu^{++} (10^{-3} M) was marked for phosphatases I and III, but moderate for phosphatase II. The hydrolysis of

* Assay conditions: 0·5 ml. of the reaction mixture contained 5 μmoles of substrate (with rice-ear and apricot) or 2·5 μmoles (with *Aspergillus*), 40 μmoles of acetate buffer and enzyme solution; *p*H of reaction mixture was 4·5 for Phos I, 5·0 for Phos II, III and Phos I″ and 3·2 for Phos I′ and II′. Reaction time; 30 min. Reaction temperature: 30° C.

p-nitrophenylphosphate by phosphatase II was inhibited by F^- in competitive fashion, while that by phosphatase III was inhibited in a non-competitive manner. The Michaelis constants of these inhibitions were $7{\cdot}4 \times 10^{-3}$ M and $3{\cdot}0 \times 10^{-4}$ M, respectively.

The phosphatase components (phosphatases II and III) showed a transphosphorylase activity of somewhat narrow acceptor specificity. Of the acceptors tested, primary alcohols were effective with phosphatase III. Inositol, adenosine and glucose did not serve as acceptors with any of the phosphatase fractions.

The phosphatase preparation from *A. niger* was resolved into one minor component (phosphatase I′) and one major component (phosphatase II′). Phosphatase I′ seems to have limited substrate specificity. Thus, only 4 out of 12 substrates tested were attacked with measurable rapidity. The preferential high activity towards α-galactose-1-phosphate as contrasted with the inertness for α-glucose-1-phosphate appears worthy of note (Table 1). In contrast, phosphatase II′ showed broader specificity, all the substrates tested being hydrolysed more or less rapidly. The *p*H optima for phosphatases I′ and II′ were 3·2. Both these activities were abolished by Mo^{++} (2×10^{-3} M), but not or scarcely inhibited by other divalent cations such as Mg^{++}, Mn^{++} and Cu^{++} (each of 10^{-3} M). Even a very low concentration of Hg^{++} (2×10^{-5} M) inactivated phosphatase I′ but not phosphatase II′.

The phosphatase preparation from apricot kernels could not be sharply resolved under the present experimental conditions. Although the homogeneity of this phosphatase I″ is questionable, it easily hydrolysed phytin, arylphosphates and all the hexosemonophosphates except α-glucose-1-phosphate, which is regarded as physiologically important in higher plants. In this respect, this phosphatase is similar to phosphatase III of rice and phosphatase I′ of *A. niger*. The fact that the sugar phosphates of β-D-series were more rapidly hydrolysed than α-glucose-1-phosphate has recently been reported also for a highly purified phosphatase of *Phaseolus aureus*[10]. Phosphatase II′, in contrast to other phosphatases tested in this investigation, acts on α-glucose-1-phosphate as easily as on other hexosemonophosphates, its activity being scarcely affected by the differences in the structure of substrates.

From results thus obtained, it may be concluded that the plant phosphatase from each source is, in general, composed of more than one isozyme of different range of specificity. Thus, one of them is capable of attacking a wide range of esterphosphates including arylphosphates, phytin, and other phosphatemonoesters, while in the other the activity is limited to only few phosphates.

We thank Dr. Elwyn T. Reese, Quartermaster Research Center, Natick, for his advice.

ETHOLOGICAL CHANGES IN *Anopheles pseudopunctipennis* IN MEXICO AFTER PROLONGED USE OF DDT

By PROF. A. MARTINEZ-PALACIOS

Comision Nacional para la Erradicacion del Paludismo, Lieja 8, Mexico 6

AND

DR. J. de ZULUETA

World Health Organization, Palais des Nations, Geneva

THE progress of the malaria-eradication campaign in Mexico during recent years has revealed that in certain areas malaria transmission has persisted despite adequate DDT spraying and in the absence of physiological resistance to this insecticide among the vectors. Investigations carried out in these problem areas, particularly in the state of Oaxaca[1], showed that the main cause accounting for the persistence of transmission was the behaviour in relation to DDT of the two local vectors —*A. albimanus* and *A. pseudopunctipennis*. The females of both species were able to penetrate the DDT-sprayed houses, bite the inhabitants inside them and escape without having picked up a lethal dose of insecticide.

When it became clear that behaviour of mosquitoes was an important factor in the persistence of transmission, the question arose as to whether the behaviour observed had existed before the introduction of DDT or was a development brought about by the prolonged use of the insecticide. In a country-wide campaign, such as that carried out in Mexico, all human dwellings in the malarious territory are regularly sprayed. This means in practice that the finding of an area untouched by insecticides where the original behaviour of vectors can be examined is virtually impossible. What can be done, and in fact was done in the present case, was to compare existing behaviour patterns with previous observations on the subject.

Downs and Bordas[2,3] examined the behaviour of *A. pseudopunctipennis* in sprayed and unsprayed huts in Acatlipa, a village of the State of Morelos considered as representative of conditions in the Mexican plateau. Experimental huts of mud walls and thatch roofs, similar to those described by Muirhead-Thomson[4] in Africa, were used in this work. Preliminary work had indicated that the use of baffles or louvres easily deterred the approaching *A. pseudopunctipennis* from entering the huts but that an L-shaped tunnel permitted their entry and at the same time prevented their escape. The L-shaped tunnel proved very useful for examining the entry pattern of *A. pseudopunctipennis*, and the egress was investigated by means of an exit trap fixed to the door of each hut. Observations on behaviour in untreated huts were made in 1949[2] and on the effect of DDT and BHC in 1950[3]. Eleven years later huts Nos. 1 (DDT) and 2 (control) of Downs and Bordas were still standing and it was decided to repeat the original observations to determine whether the prolonged use of DDT (Acatlipa had been sprayed since 1944) had produced any ethological changes in the local *A. pseudopunctipennis*.

The two huts had their mud walls replastered and their thatch roofs renewed and were fitted with L-shaped entry tunnels and exit traps identical to those used in the investigations of 1949–50. Throughout the present investigations the huts were operated 4 nights every week from dawn to dusk—weeks of entry captures alternating with weeks of exit collections. In the former the mosquitoes were caught at the time they reached the entry tunnel (as had been done in the earlier investigations) and in the latter they were removed every hour from the exit trap. In both types of captures counts were made of mosquitoes found dead on the floor.

Observations were made for a period of six weeks before spraying hut No. 1, using DDT water-dispersible powder at the dosage of 2 g/m^2 as had been done in the 1949–50 investigations. Hut No. 2, which had served then as control, was again left unsprayed and served once more as comparison hut. Collections were made for another period of six weeks, after which hut No. 1 was replastered and its thatch roof was changed before it was sprayed again using the same DDT formulation and dosage as in the first spraying. Eight months later a new series of captures of incoming and outgoing mosquitoes was carried out for another period of six weeks. Conditions in these last captures produced the same results as Downs and Bordas's investigations[3] regarding season and time of spraying. According to their published records[3], only exit captures were made after spraying, and for this reason in the comparison of Downs and Bordas's and our own results given in Table 1 only results from exit captures are given.

Table 1. RESULTS OF CAPTURES OF *A. pseudopunctipennis* IN EXPERIMENTAL HUTS AT ACATLIPA (MORELOS)
(Exit trap and floor collections)

		Hut No. 1 (DDT)		Hut No. 2 (control)	
Time after spraying	No. of captures	No. of males	No. of females	No. of males	No. of females
Original experiments of Downs and Bordas, April–July 1950					
8–10 months	21	670	510	1,185	907
Present observations, July 1962–*August* 1963					
Before spraying	12	444	438	367	412
2–35 days	12	425	374	315	256
8–10 months	12	353	245	338	252

As can be seen from these results, the number of mosquitoes caught in huts Nos. 1 and 2 before DDT spraying was very similar, and this, it should be added, is in agreement with what had been observed by Bordas and Downs[2]. After the introduction of DDT, however, an important difference is noticeable between the early investigations and the present ones. In the Downs and Bordas[3] observations the number of males and females of *A. pseudopunctipennis* caught after spraying in hut No. 1 was considerably lower than in hut No. 2. The treated hut caught only 65·7 per cent of the males and 56·2 per cent of the females caught in the control hut. In the present observations there was no reduction in the number of *A. pseudopunctipennis* caught in the DDT-treated hut. As Table 1 shows, there was in fact an increase in the number of males and females caught in the treated hut immediately after spraying. A slight reduction, it is true, was observed 8–10 months after treatment, but if the total numbers caught in each hut are added up it will be seen that the treated hut caught slightly more mosquitoes than the unsprayed hut. This, as pointed out before, is in strong contrast with the observations of Downs and Bordas[3].

Although ingress captures do not appear to have been made by these investigators after spraying the huts, they were made in the present studies both before and after spraying. Their results confirm the lack of a reduced entry in hut No. 1 after spraying. Ingress captures in hut No. 1 yielded 258 males and 276 females immediately after spraying and 212 and 256 males and females respectively, 8–10 months after. Corresponding figures for hut No. 2 (control) were 317 and 307; 168 and 201. There seems to be a slight reduction in numbers in hut No. 1 immediately after spraying; but this is compensated by a small increase 8–10 months after spraying. Altogether more mosquitoes were caught in the treated hut than in the control, as was the case with the exit trap captures. Here it should be pointed out that in the ingress captures mosquitoes are caught (by the men in charge of the captures) at the very moment they reach the ingress tunnel so that an unrecorded escape from the huts (a possibility in the exit captures) is ruled out here.

The complete lack of deterrency, a term proposed by Zulueta and Cullen[5] to embrace all possible causes that prevent mosquitoes from entering sprayed structures, is a remarkable finding, particularly when it is considered that it was observed among mosquitoes which for the most part were seeking shelter and not a blood meal (for example, males and engorged females). A behaviour like this suggests immediately a development of physiological resistance, but periodical checks on the susceptibility of the local *A. pseudopunctipennis* gave results which indicated normal susceptibility of the species to DDT. If the susceptibility under test conditions seemed to be unchanged the same cannot be said of the lethal effect produced by DDT in the treated hut. Immediate mortality in hut No. 1, based on numbers of mosquitoes dead at the time of collection (window trap and floor collections), was in the Downs and Bordas[3] observations 49 per cent in males and 85·9 per cent in females. Corresponding figures in the present observations were 45·6 per cent and 59·6 per cent soon after spraying and 34·3 per cent and 44·1 per cent 8–9 months after spraying. These results seem to indicate that, in spite of unchanged susceptibility, *A. pseudopunctipennis* avoided better the lethal effect of DDT in 1962 and 1963 than it did in 1950. As in the case of deterrency, a change in behaviour seems to have taken place here after eleven years use of DDT.

The changes observed in Acatlipa are very similar to those noted by Trapido[6,7] in the Chagres River of Panama, where after six years use of DDT, and in the absence of physiological resistance, there was an increase in the number of *A. albimanus* entering treated houses and in their survival inside them. The similarity of these findings with those of Acatlipa makes it likely that the same situation may exist in other countries where, in spite of normal susceptibility of the vectors, the effectiveness of DDT seems to have been blunted after prolonged use of the insecticide. Their changes of behaviour may provide the clue to difficulties and failures.

We thank Drs. E. Bordas (Distribuidora Shell de Mexico) and W. G. Downs (Rockefeller Foundation, New York) for their advice and assistance.

EFFECT OF SOIL/SOLUTION RATIO ON DETERMINING THE CHEMICAL POTENTIALS OF PHOSPHATE IONS IN SOIL SOLUTIONS

By S. LARSEN and A. E. WIDDOWSON

Soil Science Department, Levington Research Station, Ipswich (Fisons Fertilizers, Ltd.)

SCHOFIELD[1] suggested that an index of soil phosphate availability could be given by the negative chemical potential of monocalcium phosphate—the 'phosphate potential'—defined as $(\frac{1}{2}p\mathrm{Ca}+p\mathrm{H_2PO_4})$ and determined in a 0·01 M calcium chloride extract. Aslyng[2] found, however, that this potential varied markedly with the soil/solution ratio and he attempted to correct for this 'dilution effect' by extrapolation of his experimental results to 'zero dilution'; others[3,4] have adopted this procedure. However, this is not a justifiable correction because, as shown by Aslyng's own results and those of others[5,6], there is no approach to a limiting value towards zero dilution.

Larsen and Court[6] suggested a number of possible explanations for the effect of soil/solution ratio on the phosphate solubility but were unable to decide which was operative. Olsen *et al.*[7], using soils comparatively rich in soluble phosphate (about 100 times more than in most other soils), found that the negative dicalcium phosphate potential ($p\mathrm{CaHPO_4}$) of the 0·01 M calcium chloride extracts decreased with the amount of soil in the suspension. They equilibrated the soils with calcium chloride for 4 days at a constant carbon dioxide pressure and measured the concentration of bicarbonate ions in the extracts. This was found to increase with the amount of soil and they attributed the increase in phosphate concentration (decrease in negative phosphate potential) to the ability of carbonate ions to displace $\mathrm{HPO_4}$ ions from surfaces containing phosphate. When the chemical potential of monocalcium phosphate is calculated from the experimental results of Olsen *et al.*[7] it is independent of the soil/solution ratio (Table 1). This suggests that the observed effect of soil/solution ratio on the phosphate potential $(\frac{1}{2}p\mathrm{Ca}+p\mathrm{H_2PO_4})$ may be due to accumulation of carbon dioxide produced by microbial activity during equilibration with the calcium chloride solution, since this usually occurs in stoppered bottles mounted on an end-over-end shaker.

To test this assumption, varying aliquots of soil 5 from the experiment of Larsen and Court[6] were equilibrated for 16 h with 0·01 M calcium chloride under three contrasting conditions: (1) in stoppered bottles placed in an end-over-end shaker; (2) open bottles on a roller shaker; (3) bubbled with atmospheric air, previously moisture saturated by passing through a wash bottle containing 0·01 M calcium chloride; wrist action shaking.

From the results (Table 2) it can be seen that when stoppered bottles were used there was a reduction in pH, increase in phosphate concentration and decrease in phosphate potential with increasing weight of soil in the suspension. When the bottles were left open the same trends were observed but to a smaller degree. However, when atmospheric air was passed through while shaking, all three values became independent of the amount of soil in the suspension. Similar results were obtained with other soils.

Table 1. EFFECT OF SOIL/SOLUTION RATIO ON SOIL PHOSPHORUS SOLUBILITY *

* Soil 5 of Larsen and Court (ref. 6).

a, Stoppered bottles, end-over-end shaking for 16 h.

b, Open bottles, roller shaking for 16 h.

c, Bubbled with atmospheric air, previously moisture saturated by passing through a wash bottle containing 0·01 M calcium chloride; wrist action shaking.

In a separate experiment the amount of carbon dioxide produced by the soil was measured by absorption in sodium hydroxide using the apparatus described by Kent-Jones and Taylor[8]. The carbon dioxide pressure was calculated from the solubility of carbon dioxide in 0·01 M calcium chloride at room temperature[9], and the volume of the bottles. The results (Table 3) show that the amount of carbon dioxide produced was proportional to the amount of soil in the suspension. This suggests that the production of carbon dioxide at the individual soil/solution ratios fully explains the variation of pH with the soil/solution ratio.

Table 3. EFFECT OF CARBON DIOXIDE ON SOIL pH

g soil/ 50 ml. 0·01 M $\mathrm{CaCl_2}$	$P_{\mathrm{CO_2}} \times 10^3$	$p\mathrm{H}\alpha$	$p\mathrm{H}\beta$
1–16	(0·3)	(7·43)	(7·55)
1	2·6	7·32	7·42
2	3·2	7·22	7·32
4	5·5	7·14	7·17
8	11·8	7·01	7·07
16	21·2	6·94	7·00

$p\mathrm{H}\alpha$ measured after shaking for 16 h in stoppered bottles.

$p\mathrm{H}\beta$ measured when soil suspensions (10 g soil/50 ml. solution) were equilibrated in the presence of carbon dioxide buffers.

Figures in brackets obtained when the suspensions were equilibrated with atmospheric air.

Using the method of Pardee[10], carbon dioxide buffers were made up to give carbon dioxide pressures corresponding to those calculated when the soil suspensions were shaken in stoppered bottles. 10-g aliquots of the soil suspended in 50 ml. 0·01 M calcium chloride were then shaken overnight with an atmosphere that was in equilibrium with these buffers. The values of the soil suspensions (Table 3) compare closely with those obtained when varying soil/solution ratios were shaken in stoppered bottles without carbon dioxide absorption.

These findings have a bearing on the interpretation of lime and phosphate potentials, for the carbon dioxide content of soil air varies greatly in the field[11] because of variation in biological activity and soil aeration.

Ergebnisse der exakten Naturwissenschaften

Edited by **G. Höhler** in Collaboration with S. Flügge, F. Hund and F. Trendelenburg
Managing Editor: E. A. Niekisch

Vol. 36

In English. With 57 figures
IV, 242 pages 8vo. 1964
DM 40,–; Cloth DM 44,–

■ Leaflet on request!

With volume 36 of the "Ergebnisse", Professor Dr. G. Höhler, Karlsruhe, has taken over as the responsible editor, the editorship of this series of research-results. At the same time, the periods of publication of the "Ergebnisse" have been altered with regard to a fast and thorough information of all those interested: In future several, smaller volumes will be edited each year. In this way, workers in the field of physics at home and abroad, from research-scientists and lecturers to undergraduates, will be informed on particularly interesting subjects of physics at short intervals. In future, a large number of articles will be contributed by prominent foreign scientists, and will be published in English. In the interest of a wide circulation of the "Ergebnisse" in their new form, the price has been markedly reduced.

Contents: Some Topics Related to Unitary Symmetry. By Michel Gourdin, Université de Paris.—Meson and Baryon Spectroscopy. By B. D. Lichtenberg, Indiana University, USA. Quantum Theory of Laser Radiation. By F. Schwabl and W. Thirring, Universität Wien.

CAMBRIDGE UNIVERSITY PRESS

CHEMICAL REACTIONS IN SHOCK WAVES

E. F. Greene, *Associate Professor of Chemistry, Metcalf Research Laboratory, Brown University, U.S.A.*, and J. P. Toennies, *Physikalisches Institut der Universitat, Bonn, W. Germany*

This monograph is a revised edition of "Chemische Reaktionen in Stosswellen" which was originally published in 1959 as Volume 3 of the series "Fortschritte de physikalischen Chemie" edited by Prof. W. Jost. In it are described the theory of shock waves and the experimental methods by which they may be studied. The book is particularly intended for chemists and physicists who wish to apply shock wave techniques to their own problems. 65s. net

THE STABILIZATION OF POLYVINYL CHLORIDE

Fernand Chevassus, Ingenieur E.N.S.T., Ingenieur I.C.L., and Roger de Broutelles, Ingenieur I.C.L., Ingenieur I.F.C.

"This book is undoubtedly an important contribution to the subject. It is well written, fully documented and can be recommended as the most complete survey of the subject available." *Chemistry and Industry*. 80s. net

ACTIVATION PROCESSES IN SOLID METALS AND ALLOYS

K. A. Osipov, *A.A. Baykov Institute of Metallurgy*

In this translation from the Russian the fundamental solid-state phenomena occurring in the crystalline state are discussed with particular reference to metals and alloys. Considerable emphasis is placed on theoretical interpretation of the individual and collective physical phenomena observed in these materials. 40s. net

PRACTICAL OPTICAL CRYSTALLOGRAPHY

N. H. Hartshorne, *formerly Reader in Chemical Microscopy, University of Leeds*; and A. Stuart, *formerly Professor of Geology, University of Exeter*

An introduction to the study of the optical properties of crystals in transmitted light by means of the polarizing microscope. The authors have taken great care to show the beginner exactly how to proceed by giving full practical details and many illustrative examples. 40s. net

QUANTITATIVE AND DYNAMIC ECOLOGY

Kenneth A. Kershaw, *Lecturer in Ecology, Imperial College, London*

This book presents the general theoretical concepts that have been formulated in relation to plant ecology together with the approaches and statistical methods that have been used in developing these concepts. It will be of great interest to students and research workers in Biology, Botany and Forestry. September. 30s. net

B.S.C.S. BLUE VERSION

American Biological Sciences Curriculum Study

TEACHER'S GUIDE

All those concerned with teaching Biology at school or university who know of the B.S.C.S. Blue Version, will be fascinated by this book written specially to accompany it.

This *Guide* contains a detailed discussion of the textbook, reference lists, answers to questions, detailed information for setting up and carrying out each investigation, and suggestions for planning the course for those who are still a little hesitant of introducing the 'modern approach' to their students. Ready September. 25s. net

MOLECULES TO MAN (Text and Laboratory Manual)

This remarkable book contains not only the text but also laboratory investigations in the one volume. It will be of great value with all 'A' level work in Biology, Botany and Zoology, and will also be useful in first year university courses. 55s. net

PESTS OF FIELD CROPS

F. G. W. Jones, *Head of Nematology Department, Rothamsted Experimental Station*; and Margaret G. Jones

This is the only book for many years to cover the whole range of animal pests. It is divided according to zoological groups but chapters are devoted to characteristics of plant groups concerned in pest attack and the relative importance of various pests. Methods of control and pesticides are also discussed. 50s. net

AN INTRODUCTION TO AGRICULTURAL CHEMISTRY

Third Edition

By the late N. M. Comber, *Professor of Agricultural Chemistry*, J. S. Willcox, *Senior Lecturer*, and W. N. Townsend, *Lecturer in Agricultural Chemistry in the University of Leeds*

The new edition of this well-known textbook once again presents an up-to-date survey of the salient features of a scientific study of soil science and animal nutrition in one volume. The section on Fertilisers has been integrated with that on Soil in order to avoid repetition of ideas and to emphasize the fact that fertilisers are designed to be used to supplement plant nutrient elements already present in the soil.

IMMUNOLOGY

David F. Gray, *Assistant Professor of Bacteriology, University of Melbourne*

A comprehensive, sequential, up-to-date outline of the fundamental aspects of immunology and serology which highlights current theories and research in antibody production, cellular immunity, immunological tolerance, surgical grafting, etc. The author proposes a new genetic-instructive theory to account for antibody production and cellular immunity. 24s. net

The Schenkman Story

People wrote us letters when we started. They continue to write us letters, and even book reviews now. It is about time that we wrote an Open Letter of our own.

Schenkman Publishing Company was founded in 1961. It has from its birth enjoyed an unusual amount of support and involvement on the part of the academic community. The Company has over 200 Planning Consultants in eight different disciplines, and at universities and colleges throughout this and other countries. A professor of sociology (University of California) is "delighted to be affiliated with you in an enterprise that has not only heart but soul." A zoologist Planning Consultant wrote us (in 1962), "Starting a publishing house from scratch is a brave act indeed and I wish you luck, money, and good titles in about equal proportions. In these days of monstrous computer-directed organizations, the thought of a man starting independently with nothing more than initiative, guts, and ideas sounds utterly incongruous. Yet that's just the sort of anachronism that's going to pull us all out of the hole we're in." And another zoologist, this one at the University of London, thinks, "This is a really well thought out approach from which I hope great things."

Two years ago, *Publishers' Weekly* gave space to the Schenkman story, announcing the founding of S.P.C. We quote from the *P.W.* news columns :

> "A new college textbook firm, the Schenkman Publishing Company, has been formed in Cambridge, Mass., as an unusual venture in cooperation between publishing and the college academic community . . .
>
> "The Company has appointed eight 20- or 24-man boards of planning consultants in each of the major subject fields in which the firm will publish books: biological sciences ; physics and astronomy ; psychology and educational psychology ; sociology ; anthropology ; history ; political science ; and economics.
>
> "The president of the company is Alfred S. Schenkman, formerly editor for social sciences at Addison-Wesley and, prior to that, with Rinehart & Company, Scott-Foresman and *Orient Review*. Kirtley F. Mather, emeritus professor of geology at Harvard, is chairman of the board. In explaining the formation of the company. Mr. Schenkman said, 'We have made contact in colleges and research centers throughout the country with people in the forefront of study and education in more than a few subjects, and we have invited them to join our planning boards. They will advise on overall policy-making and in their respective academic specialities . . .'."

This gives the story as of *then*. *Today* Schenkman has published ten books, with more than that number under way. Some of the first Schenkman books have come from the SPC membership, and others not. In one instance, Schenkman worked in co-operation with another organization, and this occasion of co-operation resulted in the latest SPC book—"Human Fertility and Population Problems," the Proceedings of a Seminar sponsored by the American Academy of Arts and Sciences.

Among the books published are "The Economic Impact of the American Civil War" (edited by Ralph Andreano) ; W. G. Hardy's "The Greek and Roman World," with an accompanying collection of sixty prints and commentary ; "Money," by M. L. Burstein ; "Integrating Principles of Social Psychology" (by Professors Joseph B. Cooper and James L. McGaugh) ; "Psychological Counseling in a Small College," by Professor Eugenia Hanfmann *et al.* ; "Ego Synthesis in Dreams," by Richard Jones ; Carlo L. Lastrucci's "The Scientific Approach" ; "Social Stratification : Class in America," by Professor Harold M. Hodges ; and "This Universe of Space," by Professor Peter M. Millman, also published in a British edition.

Books coming this year include "Public Health and Population Change : Research Issues in the 60's", The Proceedings of a Seminar held in June of this year by the Graduate School of Public Health, University of Pittsburgh ; "New Perspectives on American Economic Development," by Professor Andreano ; "Cause, Chance, Identity : an Introduction to Quantum Mechanics," by Professor Philip Morrison.

Schenkman books are published simultaneously in Canada by S. J. Reginald Saunders and Co., Ltd. International Sales Representatives (excepting Canada) are Feffer and Simons, Inc., New York, N.Y., whose British agents are T.A.B.S., 43 Essex Street, London, W.C.2, England.

We ourselves always answer letters written directly to us.

World Shipping: An Economic Geography of Ports and Seaborne Trade

G. ALEXANDERSSON, *Associate Professor of Economic Geography at the Stockholm School of Economics* and G. NORSTRÖM, *Assistant Professor of Economic Geography at the Stockholm School of Economics*

This book is intended first as a textbook or work of reference for students and teachers of economic geography, the economics of transportation, and related fields. Secondly, it should serve a wider public, all people interested in shipping and harbours, including shipping companies, port authorities, etc., who will find reference material in this volume which is not so readily available elsewhere.

507 pages, 132s.

Geography of the U.S.S.R.

P. E. LYDOLPH, *Professor of Geography, University of Wisconsin, Milwaukee*

Lucidly written, this self-contained text sets forth a regional and topical coverage of the physical, cultural, and economic geography of the U.S.S.R. The eleven major Russian regions are discussed first, followed by chapters that consider individual topics of cultural and economic geography; population, agriculture, industry, transportation, trade, and international relations. These topical chapters cut across regional boundaries and treat the Soviet Union as a whole in an original and logical manner. This book is well illustrated including 132 large maps, using standard Russian symbols, and many photographs.

624 pages, 83s.

Synthetic Fibers in Papermaking

edited by O. A. BATTISTA, *Manager of Interdisciplinary Research, Central Research and Development Laboratories, FMC Corporation, Princeton, New Jersey*

Presents for the first time in depth, the complete and current status of the use of synthetic fibres in papermaking. Useful technical data, market potentials and the technology of making paper and textile web products with such fibres as metal, glass and ceramics are covered in each chapter.

352 pages, 105s.

Molten Salt Chemistry

edited by MILTON BLANDER, *North American Aviation Science Centre, Canoga Park, California*

Consists of a collection of self-contained critical reviews of several aspects of the field of molten salt. It provides a single convenient reference work on the theory, structure, phase behaviour, transport properties, spectra, and thermodynamic properties of molten salts and salt vapours.

792 pages, 188s.

Analysis and Characterization of Oils, Fats and Fat Products

Volume I

edited by H. A. BOEKENOOGEN, *Professor, Technical University, Eindhoven*

This is the first volume in a new series which is being published to help those engaged in the investigation of oils and fats in the widest possible sense. It is designed to satisfy the long-felt need for an up-to-date survey of the entire field, and proposes to do this by publishing from time to time collected volumes of papers by acknowledged leaders in their particular subject. The new series will also bridge the gap between industrial analytical control and scientific research, which is so often reflected in the lines along which the analysis of fats has developed. The great industrial importance of analytical methods in the field of oils and fats; the rate of development of analytical methods; and above all continuously expanding specialization combine to make this general survey important and necessary.

405 pages, 84s.

Plasma Waves

J. F. Denisse, *Observatoire de Paris*
and J. L. Delcroix, *Faculté des Sciences de Paris*
translated by M. Meinrich *and* D. J. B. Daniel,
General Electric Research Laboratory

Number 17 in the series *Interscience Tracts on Physics and Astronomy,* edited by R. E. Marshak, University of Rochester. Containing a systematic and concise description of waves in plasma, it treats the theory of small amplitude plane waves in an infinite plasma.

160 pages, 59s.

Digital Magnetic Recording

A. S. Hoagland, *Advanced Systems Development Division, IBM Corporation*

This is a pioneer work devoted exclusively to the fundamentals of digital magnetic recording. Digital magnetic recording is radically different from conventional sound or video magnetic recording. It is also essentially the exclusive means to realize the mass storage of data for computer systems. This volume has the character of a reference work, stressing principles, and is not tied to current or past practices. Transient rather than steady state analytical techniques are used.

154 pages, 60s.

Guide to Information Sources in Space Science and Technology

edited by B. M. Fry, *Office of Science Information Service, National Science Foundation, Washington, D.C.*
and F. E. Mohrhardt, *National Agricultural Library*

This is the first volume in the new series *Guides to Information Sources in Science and Technology,* edited by the same authors. This series of literature guides will aim to give research workers, information specialists, special librarians and students in major areas of science or technology explicit and comprehensive coverage of all sources of information and data in their fields, published and unpublished, domestic and foreign. When complete, the series will be an effective " science information centre." The first volume has been compiled and edited with the aim of providing an introductory guide to continuing sources of information in fields of space science and technology together with a representative working collection of the literature. This guide attempts to exploit all current sources, both published and unpublished, and to serve as an interdisciplinary and specialized information centre for the researcher who wishes to proceed further in his own or related field.

512 pages, 75s.

Symposium on Optical Masers

edited by Jerome Fox, *The Polytechnic Institute of Brooklyn*

Volume 13 in the series Microwave Research Institute Symposia. The symposium, held in New York City, April 16–18, 1963, depicts the rapidly advancing optical maser field in midstride, presenting a balanced display of its electrodynamical, statistical, material, and practical features. It attempts a comprehensive integration of the physics and technology bearing directly on the discovery, theory, and application of maser phenomena at optical and infrared frequencies.

677 pages, 113s.

Casebooks in Production Management Series

Volume I

Basic Problems, Concepts and Techniques

edited by A. R. Dooley, *Associate Professor of Business Administration*
R. E. McGarrah, *formerly Associate Professor of Business Administration*
J. L. Kenney, *Assistant Professor of Business Administration*
R. S. Rosenbloom, *Assistant Professor of Business Administration*
C. W. Skinner, *Associate Professor of Business Administration*
P. H. Thurston, *Associate Professor of Business Administration*
all of Harvard University Graduate School

This is the first volume of a five-volume work of text and cases designed for an introductory course in production or management. The cases offer a realistic view of management problems and focus upon management activities—decision making, planning and implementing—which must underlie effective utilization of the technological, economic and human resources of any company. The first volume offers a cumulative set of experiences in decision making starting from an analysis of the single unit (machine or workstation), and proceeding through the analysis of flow problems to management of the total operating situation. Discussion is based on the product and process technologies of the metalworking industry.

Automatic methods in volumetric analysis

D. C. M. SQUIRRELL

To be published in September, and emphasizing methods while paying due attention to instruments, this book illustrates the types of volumetric analysis in which automation has advantages. It gives its methods in enough detail for readers to be able to evaluate them for particular applications. Dr J. Haslam has contributed a preface.

THE NUCLEOHISTONES

Edited by JAMES BONNER, California Institute of Technology and PAUL O. P. TS'O, Johns Hopkins University

This book is the outcome of the First World Conference on Histone Biology and Chemistry held in April, 1963, to uncover the role of histones in determining the organization of DNA inside the chromosomal superstructure; to discuss the chemistry of histones and their interaction with DNA; and to explore the significance of histones in molecular biology. Directed to the student or research worker in biology, biochemistry, or biophysics, it is a preview of the problems important to the future course of research in nucleohistone biology and chemistry. *$12.75*

WATER AND SOLUTE-WATER INTERACTIONS

by J. LEE KAVANAU, University of California at Los Angeles

This comprehensive review and discussion of the current theories and status of research in the fields of water structure and solute-water interactions will have general interest for researchers and advanced students in many areas of the physical, chemical, and life sciences. The topics discussed are briefly as follows: Ice; Vacant-lattice-point, flickering-cluster, water-hydrate, and distorted-bond models of water structure; Problems of short- and long-range ordering of water; Proton mobility; Ion-water interactions: anions versus cations, net structure-making versus net structure-breaking, shortcomings of electrostatic models, consequences for proton exchanges. *$5.50*

PITUITARY-OVARIAN ENDOCRINOLOGY

Edited by RALPH I. DORFMAN, Worcester Foundation for Experimental Biology and MANUEL NEVES e CASTRO, Portuguese Cancer Institute

"... This volume contains not only a relatively detailed description of the biosynthesis of androgens and estrogens but is replete with clinical information for the practising gynecologist. The very latest ideas concerning causes and treatment of the polycystic ovary-hirsutism syndrome are discussed with unusual clarity. Chapters on the stimulation and inhibition of ovulation are extremely well done.... The conclusion one must accept after reading this volume is that cooperation between the basic medical scientist and clinician is highly profitable in both theory and practice. Both gynecologist and endocrinologist will benefit by this publication." Albert J. Boyle, *Record of Chemical Progress.* *$14.95*

STRUCTURE AND FUNCTION IN BIOLOGICAL MEMBRANES, VOL. I

by J. LEE KAVANAU, University of California at Los Angeles

A detailed treatment of structural and functional aspects of biological membranes including a monographic development of the author's theories. The book also presents a comprehensive advanced treatment of current theories and the status of research in the fields of: the molecular and interfacial chemistry of lipids, proteins, and lipid-protein complexes; the properties of micelles, monolayers, and water; and solute-water and ion-ion interactions. *$10.50*

MOLECULAR COMPLEXES OF ORGANIC CHEMISTRY

by L. J. ANDREWS and R. M. KEEFER, University of California, Davis

Intended for research chemists and advanced students of organic and physical chemistry, this monograph presents a general survey of the recent work in molecular complexes of the donor-acceptor type, with emphasis on those phases in which organic chemists are most likely to be interested. Topics such as complex geometry and complexes in relation to reaction mechanism are treated in detail. Background material concerning topics such as spectra of complexes, bonding in complexes, and the thermodynamics of complex formation is presented but not in a mathematically rigorous fashion. There are abundant key references to current literature in the field. *$8.75*

INTERPRETATION OF MASS SPECTRA OF ORGANIC COMPOUNDS

by HERBERT BUDZIKIEWICZ, Research Associate, Stanford University. CARL DJERASSI, Professor of Chemistry, Stanford University. DUDLEY H. WILLIAMS, Churchill College, Cambridge, England

"... Several series of classes of organic compound are discussed and many typical examples are considered in detail so that the fragmentation patterns of other members of these series will be interpreted, it is hoped with relative ease. The compounds dealt with are carbonyl compounds, alcohols, ethers, thioethers, mercaptans, amines, amides, cyanides, isothiocyanates, alkyl halides, bicyclic ketones, aromatic hydrocarbons and their functional derivatives, tropones, tropolones, and finally, certain aromatic heterocycles.... On all counts this volume can be recommended as fulfilling all it sets out to do: to give an explanation and interpretation of a wide and representative set of mass spectra of organic compounds in terms which will be appreciated by organic chemists." A. W. Johnson, *Chemistry and Industry.* *$8.75*

STRUCTURE ELUCIDATION OF NATURAL PRODUCTS BY MASS SPECTROMETRY, VOLUME I : ALKALOIDS

by HERBERT BUDZIKIEWICZ, CARL DJERASSI, DUDLEY H. WILLIAMS

Of interest to every organic chemist, this book illustrates the dramatic progress which has been made during the past three years in the rational use of mass spectrometry for the structure elucidation of complex natural products. Main emphasis is placed on the extensive use of isotope labelling and mechanistic considerations. This volume amply demonstrates the colossal impact of the mass spectrometric method in studying polycyclic organic compounds. *$10.50*

STRUCTURE ELUCIDATION OF NATURAL PRODUCTS BY MASS SPECTROMETRY, VOLUME II : STEROIDS, TERPENOIDS, SUGARS AND MISCELLANEOUS CLASSES

by HERBERT BUDZIKIEWICZ, CARL DJERASSI, DUDLEY H. WILLIAMS

Presents an up-to-date coverage of the important classes of natural products that have been exposed to mass spectral scrutiny, with the exception of alkaloids, covered in Vol. I. Emphasis is placed upon the localization of the positive charge in a molecular ion containing a suitable heteroatom or aromatic system. This approach leads to a self-consistent rationale for the interpretation of mass spectra of natural products. *$10.50*

COMPUTATION OF MOLECULAR FORMULAS FOR MASS SPECTROMETRY

by JOSHUA LEDERBERG, Director of the Kennedy Laboratories for Molecular Medicine, Stanford University

A compact handbook convenient for laboratory use, this modern analytical method requires the repeated interpretation of precise molecular weights as possible formulas of organic molecules. With a new approach and these brief, computer-generated tables, the user can interpret over 500,000 possible values, including most formulas up to weight of 1,000 and beyond. *$4.25*

McGRAW-HILL

International

Student ISE *Editions*

McGraw-Hill's International Student Editions programme is probably the most revolutionary textbook development ever attempted by any publisher. It presents high-quality, unabridged reprints of internationally-established textbooks at approximately 40% less than their original price. Following on the outstanding success of the 170 books already on the market, a further 30 titles are soon to be added to the series. Areas of study covered by the ISEs include the Pure, Applied and Social Sciences, Business and Economics, and Technology.

30 NEW TITLES

Biology

McCOLLY *An Introduction to Agricultural Engineering* **40s** (68s original price)
YOUNG *Witton's Microbiology 3/e* **45s** (62s)
PRESCOTT *Industrial Microbiology 3/e* **70s** (£6 15s 6d)

Chemistry

BARROW *Introduction to Molecular Spectroscopy* **40s** (83s 6d)
SIENKO *Experimental Chemistry 2/e* **19s 6d** (27s)

Civil Engineering

CHOW *Open-Channel Hydraulics* **56s** (£6 12s)

Economics

DORFMAN *Linear Programming and Economic Analysis* **40s** (88s)
JOHNSTON *Econometric Methods* **32s 6d** (58s)
TAYLOR *A History of Economic Thought* **42s 6d** (66s)
DERNBERG *Macro-economics 2/e* **32s 6d** (54s)

Education

HURLOCK *Adolescent Development 2/e* **40s** (58s)

Electrical Engineering

KIVER *Transistors 3/e* **37s 6d** (50s 6d)
PLONSEY *Principles and Applications of Electromagnetic Fields* **45s** (99s)

LEIGHTON *Principles of Modern Physics* **56s** (97s)
SEITZ *The Modern Theory of Solids* **56s** (£5)

NEW AND FORTHCOMING BOOKS FROM BUTTERWORTHS

Animals and Plants of the Cenozoic Era

By RONALD PEARSON, M.A., Ph.D., F.R.E.S., F.Z.S.

A survey of the information which botanists, geochemists, geologists and zoologists have provided on the faunal, floral and climatic events of the Age *of Mammals*, providing for the first time a complete picture of the subject as a whole.

236 pages Illus. 55s.

Cell *p*H

By E. EDWARD BITTAR, M.D.

A basic reference for practitioners and research workers in every branch of medicine and related fields of chemistry and biology. It is the only monograph of its kind dealing specifically with Cell *p*H.

129 pages Illus. 37s. 6d.

High Temperature Technology I.U.P.A.C.

Twenty papers presented at an International Symposium on High Temperature Technology held in California in September 1963, under the patronage of the International Union of Pure and Applied Chemistry.

approx. 600 pages Illus. 130s.

The Periodic Table

Third Edition. By D. G. COOPER, B.Sc., F.R.I.C.

The third edition of a well-known text which provides the student with a summary of the facts of inorganic chemistry, integrating them by use of the atomic theory and the framework of the periodic table.

111 pages Illus. 10s. 6d.

Laboratory Techniques in Botany

By M. J. PURVIS, R.H.S., D. C. COLLIER, and D. WALLS, A.I.S.T.

A textbook and practical manual covering all the main techniques and apparatus used in a botanical laboratory. The second volume in the *Laboratory Techniques Series.*

371 pages Illus. 57s. 6d.

Peroxidase

By B. C. SAUNDERS, C.B.E., M.A., Ph.D., Sc.D., D.Sc., F.R.I.C.
A. G. HOLMES-SIEDLE, M.A.(Sc.)., Ph.D. and
B. P. STARK, Ph.D.

A comprehensive and integrated guide to the facts and theories connected with the enzyme peroxidase and its related catalysts.

282 pages Illus. 60s.

An Introduction to Radioactivity

By ERIC NEIL JENKINS, B.Sc., M.Sc.

A new and up-to-date textbook for students of physics and chemistry at schools, technical colleges and universities.

156 pages Illus. 30s.

Semiconductors

By HORST TEICHMANN, Dr.Ing.habil.

Based on the electron theory of the electrical conductivity of metals, this textbook for intermediate and advanced students, bridges the gap between purely technical literature and that which is scientific and theoretical.

150 pages Illus. 22s. 6d.

88 KINGSWAY, LONDON, W.C.2. **BUTTERWORTHS**

HANDBOOKS

HANDBOOK OF INDUSTRIAL INFRARED ANALYSIS

by **Robert G. White.** A practical, self-sufficient handbook in the techniques of industrial infrared analysis. The volume has been written with the intent of answering in concise, convenient terms, the thousands of questions that are posed by industrial analysts or students who intend to work in industrial laboratories. It is the single best tutorial reference to the qualitative and quantitative analysis of the multitude of materials essential to industry. Approx. 400 pages $19.50 Plenum Press

INFRARED BAND HANDBOOK

Edited by **Dr. Herman A. Szymanski.** Over 8500 band positions of organic and inorganic compounds are tabulated according to wavelength of their infrared absorption spectra. Thus, by referring to the Handbook, it is possible to find compounds at any selected wavelength having at least a medium-intensity band at that wavelength. Data retrieval time is much shorter than with any other method because in most cases the wavenumbers of the listed band are reported to an accuracy of 1cm^{-1}, a great improvement over previous systems. Supplements 1 & 2 bound in one volume cover a range of 15-25 microns (a region especially important in compound identification). Plenum Press **INFRARED BAND HANDBOOK** 440 pages $35.00

SUPPLEMENTS 1 & 2 Approx. 250 pages $15.00

HANDBOOK OF X-RAY STRUCTURE ANALYSIS OF POLYCRYSTALLINE MATERIALS

Edited by **L. I. Mirkin.** In this exceptional volume, the calculated and experimentally determined constants and data essential to the production and interpretation of x-ray patterns of polycrystalline materials have been collected from the world literature and are presented in a single volume in tabular, graphic and nomographic form organized in the sequence in which the analysis is usually performed. Some tables are published here for the first time; many have been expanded especially for the English edition. Over 700 pages Translated from Russian $35.00 Consultants Bureau

PLENUM PRESS HANDBOOKS OF HIGH-TEMPERATURE MATERIALS, 1 & 2

Forewords by Dr. Henry Hausner

NO. 1 – MATERIALS INDEX by Peter T. B. Shaffer. Offers data on the general, chemical, electrical, mechanical, nuclear, optical, structural, and thermal properties of approximately 520 refractory materials arranged by compound. Compounds listed include borides, carbides, nitrides, oxides, silicides, mixed oxides, mixed carbides, and elements. 782 pages $17.50 Plenum Press

NO. 2 – PROPERTIES INDEX by G. V. Samsonov. Classifies 600 refractory compounds systematically arranged by the following properties; crystal-chemical, thermal, thermochemical, electrical, magnetic, optical, mechanical, chemical and refractory. An invaluable appendix gives the most up-to-date phase diagrams of systems in which refractory compounds are formed Revised by the author to include work up to late 1963. Translated from Russian 400 pages $22.50 Plenum Press

BRITISH ASSOCIATION MEETING IN SOUTHAMPTON

SCIENCE AND BEHAVIOUR

By The Right Hon. Lord BRAIN, F.R.S.

President of the British Association

Introduction

IT is with great pleasure that the British Association comes back to enjoy once again the hospitality of Southampton. Since we were last here in 1925, the University College has become the University and the town a city, and Southampton to-day looks ahead to new and great challenges to its civic and educational life.

It is interesting to look back at former meetings of the Association which have been held here. We hear a good deal to-day about the accelerating acceleration of scientific knowledge and development; but a review of the Association's past would suggest that there is also a factor of inertia to be taken into account. In 1882 when the 52nd meeting was held in Southampton, the report says that "this year the Channel Tunnel Company sought to obtain powers from Parliament to enable it to make a tunnel to connect this country with France by a railway beneath the channel", and one speaker advocated both metric measurements and decimal coinage. Going even further back, to the 1846 meeting, we find Dr. Laycock directing attention to "some diseases resulting from the immoderate use of tobacco", and mentioning particularly "congestive inflammation of the . . . bronchial lining of the lungs". In the same year, there was a notable communication by Dr. Carpenter "on the physiology of the encephalon" which is relevant to my subject. Carpenter drew from comparative anatomy some conclusions about the role of what he called the sensory ganglia, situated in the base of the brain, in both sensation and emotion—ideas which were not to find full confirmation until the present century.

In choosing to talk about "Science and Behaviour" I have several objects in view. The primary one of course is to fulfil the aim of the British Association to bring some scientific facts before a wider public than would normally hear about them. But this at once raises a problem of scientific communication. As science becomes increasingly specialized, it seems to me that two kinds of scientific communication are required. First, there is the obvious need to tell people about what is going on in particular sciences, but there is also, surely, an equal need to show how researches in many different sciences may be related to one another. The difficulty is that such an enterprise does not fall within the scope of any individual specialist, and we lack specialists in generalization. To try to give such a satellite view is to court attack from those over whose territory one flies in one's survey. Nevertheless, I propose to make the attempt.

By behaviour I mean the reactions of living animal organisms to their environment. As human beings, we are increasingly occupied with problems arising out of our own behaviour: one need look no further than the addresses of my presidential predecessors during the past decade to illustrate this. Not unnaturally, perhaps, we tend to interpret human behaviour exclusively in human terms, and there is no lack of such interpretations. I believe, however, that what man has in common with other animals may prove to be just as important for our understanding of his behaviour as are his distinctively human characteristics. Indeed, I think it will illuminate our problems. I propose, therefore, to try to present a biological view of behaviour, including our own. This should not be a narrow view, if, as I hope to show, it embraces all aspects of life.

Behaviour as Response to Environment

The study of the behaviour of sub-human mammals, birds, fishes, and insects, has one great advantage over the study of human behaviour. Organisms with comparatively simple nervous systems may exhibit quite complex behaviour, but in studying such creatures it is much easier than in the case of man to isolate the factors involved. At the same time there are cardinal differences between the environment of man and that of all other living creatures. The environment to which any sub-human living organism reacts is a much simpler one, because it is a more narrowly selected environment—selected by the innate structure of its sense organs and, still more, its nervous system. Each living organism, through natural selection, has become equipped to respond to those environmental stimuli which are biologically important to it. For example, the study of sex-attractant odours in insects[1] has shown that these may be so highly specific that a very slight change in their chemical structure may make them less effective or even quite ineffective. So sensitive is the insect's sense of smell that it will respond to a few molecules of the substance. Bats use ultrasonic vibrations like radar to detect the insects on which they prey; but there are noctuid moths which have evolved so that they react selectively to the ultrasonic cries of the bats[2].

Since these moths have only two nerve fibres connecting their hearing organ with their nervous system, it has been possible to make a detailed study of their nervous responses to the bat's cry, and to show how they receive information about the distance of the bat, and the direction of its flight; and that their movement of response is modified in accordance with the information they receive. Much work done by ethologists throws light on the perceptual element in the behaviour of a large range of living creatures.

But this highly selective response to particular features of the environment is far more than a simple reflex reaction to one sensory modality. Even those organisms with a comparatively elementary nervous system exhibit very complex behaviour. Thus it has been shown that the fruit-fly, when using its sense of smell to find its way to a substance on which it feeds, can do this only with the aid of visual observation of the ground, without which it cannot 'know' from which direction the wind is blowing and so cannot fly up-wind in the direction from which the attractive scent is coming[1].

Perhaps the most notable examples of the complexity of the factors influencing behaviour are to be found in the way in which honey-bees orientate themselves in relation to a source of honey, and communicate information about this to their fellow workers; and also in the direction-finding methods of migrating birds. Dr. W. H. Thorpe[3] says on this subject: "In both there is presumably an innate appreciation of direction and speed of movement of the sun, together with an accurate internal clock. In both there is the innate ability to relate a 'desired' direction to the spacetime standards innately provided, to extrapolate from the observed situation and to relate to it the knowledge of general topography and special landmarks gained from individual experience. In both there is an 'appreciation' of the relation between '*direction*' of a light source and the '*direction*' of a movement (foraging flight, migration flight, homing flight). But the honey-bee does better than the bird in two respects. Firstly, it can and must 'transpose' between sun direction and gravity direction, and secondly, it must be able to transmit information by transposition between foraging flight and a straight run of the dance"—which is the specially directed movement which the bee carries out on its return to the hive to convey the necessary information to its fellows. As Thorpe says, "what are we to make of the bee's brain of 2·5 mgm in view of its astounding performance?". Recent work suggests that the bee's signalling is even more complex, sound also being used to convey information about distance[4,5].

Thus the perceiving organs and the nervous system of the bees and the birds are able to obtain from their environment the kind of information which the navigator gets by using his sextant, compass and chronometer, and to process this information, and turn it into motor programmes, which result in flight in the right direction and for the right length of time.

Organization of Behaviour in the Nervous System

Now I must say something about how the animal's behaviour is organized in the nervous system. In a sense that would involve describing everything which the nervous system does, for it exists only to organize behaviour.

In outline, we begin with the sense organs, and the sensory nerves conveying information from them. Recent physiological work shows how the discrimination of different features in the environment begins with the structure and activities of the sense organs. The retina of the frog's eye, for example, can 'distinguish' a curved edge from a sharp one[6] and the cat's retina is so organized as to react differently to movement in one direction and movement in another, bringing different nerve fibres into action in each case[7]. From the vast number of nerve impulses streaming into it from all the sensory channels, the brain makes possible the recognition of patterns, and hence of objects. If you teach animals that, if they react to a certain visual pattern, they will get something they like, you can test them with different patterns, and find out to what elements in a complex pattern they respond, and why[8].

How an animal responds to an object depends on its instinctive drives, and these are to a large extent mediated by the activity of the nerve centres situated at the base of the brain in what is in evolution its oldest part. There, in many mammals, are centres for rage or aggression, and when these are stimulated electrically or cut off from higher control, the animal exhibits all the manifestations of rage, while if they are destroyed, or cut off from communication with the rest of the nervous system, it becomes abnormally docile[9]. Fear and avoidance, feeding, and sexual and maternal activity are similarly represented in this region. So we must picture sign-stimuli being received, and the resulting information, reinforced by previous experience through memory, being brought to this part of the brain, where it rouses into action the right organizing centre to call forth the appropriate response. These centres are influenced also by internal factors. Chemical substances, such as the products of the endocrine glands, play on them and prime them; their activities are also modified by a complex system of nerve fibres which regulates alertness, attention, sleep and waking, and so consciousness itself.

Thus animals react to situations in a complex fashion, often using more than one sense. But even in the highest sub-human animals, the extent of their environment to which they react, and the range of their reactions to it, are very limited. We think in terms of sign-stimuli, such as a particular colour, shape or movement, as eliciting a behavioural response, because the scientific method seeks to isolate individual variable factors; but the sign-stimulus we isolate is part of an environmental situation, and the response is that of the animal as a whole. But we must not become too anthropomorphic, and picture birds and animals as regarding their mates or their young or their prey as though these were as coherently and enduringly objectified to them as they are to us. At present, in any event, we cannot imagine what an animal perceives; but we can avoid thinking that this is like our own ideas or experiences.

The Uniqueness of Man

This leads me to ask in what respects—important for our present purpose—human beings as animals differ from other animals.

The evolution of man has been a good deal discussed in the light of recent research, particularly in Africa. We need not now concern ourselves with the details. It seems established that at some time from half a million to a million years ago, our hominid ancestors evolved by descent from a kind of anthropoid ape not represented by any living species. A number of factors were involved in this transition, notably changes in the shape of the hand, the pelvis, the legs, and the feet. But changes in the brain were of fundamental importance, and already we can see in the brain of the anthropoid ape developments which are an important move in the direction of the human brain. In the primate brain, the occipital lobe at the back becomes enlarged to accommodate the expanding visual area, and there is also a rapid development of the temporal and frontal lobes—higher centres concerned with bringing perception, memory and the instinctive drives into relation with one another[10]. These areas are further developed in man both relatively and absolutely, with the significant expansion also of an area in the lower part of the parietal lobe, which plays an important part in speech, and the use of symbols generally[11-13].

We find, then, that the basic structure of the human brain is similar to that of other animals. We have inherited from our early ancestors the nervous mechanisms which underlie much emotional behaviour. What is distinctively human is not only the increase in the size of the brain, but also the selective development of particular areas relative to the rest. What does this mean in terms of function?

I have already shown what the honey-bee can do with its brain of 2·5 mg. The average human brain weighs 1,500 g—half a million times as much. Clearly a very small nervous system does some things very successfully. It does them well because it is the product of evolution, and in evolution nothing leaves so many successors as success. But creatures with small brains exhibit only a small number of behaviour patterns. Since each nerve cell is capable of receiving information from hundreds of others, even a small increase in the number of nerve cells in the brain greatly adds to the complexity of the interrelationships of the total number. The increase in the size of the brain and the particular development between the anthropoid apes and man are associated with a change of behaviour which is qualitatively so great that the gap between man and his immediate pre-human ancestors is greater than that between those and the lowest mammals; and it is the human brain which is responsible for this difference for, however important in human evolution may have been the development of binocular vision, the assumption of the erect posture, and changes in the structure of the hand, it was the development of the nervous system which enabled man to put these structural changes to new uses.

Beginning on the receptive side, we find in man an enormously increased visual discrimination, which is not due to better eyes, but to the better use made of them by the brain. Added to this is the greatly increased capacity for learning and memory. But the new ability, which above all others transformed an animal into a man, was the use of symbols in language. I will not stop now to discuss the much-debated question of the relationship between language and thought. The two are certainly intimately related, and without language thought cannot get very far. By means of symbols, which now include special languages and meta-languages, such as those of mathematics and logic, the mind can represent things, and the relations between them, in a world of its own, and in the absence of the things for which the symbols stand, and it can then go back to the outer world and test the results of its activities.

Just as brain development has greatly increased the range and scope of perception (that is, the receptive side of its activities), so it has enhanced the range and power of man's control over his environment. Manipulation, which literally means handling, has been extended from the simple things an ape can do with its hand to the construction of tools, which, beginning with flaked bones and chipped flints, have developed within a few millennia into the electron microscope, the radiotelescope, and the vast and powerful machines which are used to split matter into its minutest components: and this, in modern parlance, is a feed-back mechanism, for manipulation enhances perception and conversely, and symbolic languages make the whole process possible, so that man's range of action now extends from the omega particle to the planets, and his perception millions of light years further.

But this is still only half the story of human distinctiveness. Man is a social animal in a special sense. Many types of animal society exist, some, among insects, quite complex; but man alone has built up his society on the basis of language, and it is language which has made possible the unique complexity of human social relationships, out of which have sprung, among other things, the scientific achievements of which I have just been speaking: and, of course, the development of written language and printing has endowed man with a new mode of social inheritance through which ideas can survive those who produce them, and influence succeeding generations. Moreover, broadcasting has greatly multiplied the numbers to whom speech can be directly transmitted.

We see then how each expansion of one aspect of behaviour in the development of man from ape has stimulated and aided the growth of others. This is well illustrated by human emotional life. Man's increased powers of perceptual discrimination and memory unite with his capacity for symbolism to throw his feelings open not only to a vast range of experiences of things and events in the outside world, but also to his own ideas, and to both expressed and transformed in literature and art: and so man becomes self-conscious. Whether any higher animals other than man are self-conscious is a matter for speculation; but it is safe to say that man alone has an idea of himself, which plays an important part in his behaviour. In a special sense, then, man possesses two environments. There is the external environment which we all share, and an inner world, the world of the mind, private to each one of us, in which dwell our memories, thoughts, and feelings, and the outer world reflected in them. "Thus is man", as Sir Thomas Browne[14] says, "that great and true Amphibium, whose nature is disposed to live not onely like other creatures in divers elements, but in divided and distinguished worlds"; and with man's self-consciousness comes the impulse to understand himself. Can man explain himself? Is there a science of human behaviour?

Science and the Mind

Science deals chiefly with what is measurable. It observes, constructs hypotheses, and goes back to the facts, to see if it can verify them by further observations, which include experiments. How are we to measure factors in the complexity of the human mind ? Sometimes this is comparatively easy. Experimental psychology, for example, devises tests to measure human learning and memory, attention and vigilance, decision-making and skill: in his laboratory the psychologist can vary the conditions of perception, and also study how perceptual activities break down as a result of brain disease. Language and its disorders offer a particularly valuable field for psychological investigation, and here psychology joins hands with linguistics. Word-frequency studies and observations of the choice of words, when speech is disordered, may be expected to throw light on the way in which the physiological processes underlying language are organized in the brain.

But the difficulties inherent in psychological measurement are well illustrated by the problems to which intelligence tests have given rise. The intelligence tester gives the subject various tasks to perform (some involving the use of words, and some not), allots a score of marks, and compares the results with standard scores, corresponding to percentiles in a representative population. The difficulties begin when we ask what these tests are measuring, and what we are doing when we subject the results to factorial analysis. One may of course evade these questions by merely saying that the tests do no more than measure individual responses to particular problems, and render possible predictions, which experience shows to be on the whole valid. But this is to neglect the scientific value of hypothesis.

Prof. M. D. Vernon[15] directs attention to the essentially cumulative nature of mental development, which, he says, "implies that those who, in early life, acquire a richer stock of perceptual schemata and verbal labels, are better able to build up the more complex and more flexible schemata necessary for conceptual thinking". Moreover, a stimulating environment and the absence of emotional stresses during childhood are factors favourable to the development of schemata, while children who have been emotionally starved, or frustrated, have schemata which are in various ways inadequate, and fail to develop to the fullest possible extent.

But it is in the realm of human emotion and man's instinctive drives that we encounter the greatest difficulties for measurement and classification. The idea that human beings can be classified as belonging to one or other of certain psychological types goes back at least as far as the Greeks, and in such classifications stress has always been laid on their emotional reactions. But if it is hard to know exactly what we are testing, when we carry out intelligence tests, tests of emotion would seem to be even more difficult to interpret.

The analysis of human emotions seems itself to be strongly evocative of emotion, judging by the vigour with which the elaborate theoretical systems of human behaviour, which have come into existence, are attacked and defended. Since the beginnings of civilization there have been systems of belief about human nature which are unscientific, because they are unverifiable, there being no tests by which we can determine whether they are true or not. Prof. K. R. Popper[16] has pointed out, in connexion with psychoanalysis, that theories which explain everything are unverifiable. There is no means of testing them: there is no conceivable human behaviour which could contradict them. But though such theories may be unscientific, they are not necessarily valueless. The contributions which science can make to the interpretation of something as complex as human nature are at present limited, and in unscientific theories, as in art, there may be insights, intuitions and illuminations, which are of value for practice as well as for theory. But in no pejorative sense of the word they belong to the sphere of myth rather than science.

There are two aspects of the human mind which add to the difficulty of a scientific interpretation of emotions. There is in psychology a principle of indeterminacy which is of much the same kind as Heisenberg's in physics, for in an enquiry into a person's emotions, the mere fact that the enquiry is made creates an emotional reaction, so that the intervention of the observer modifies the effects of his observation.

Secondly, as has now long been recognized, the explanation which a person gives of his behaviour and his motives, though it appears to him to be both true and adequate, may omit relevant factors because he is unconscious of them. The existence of what is called the unconscious mind was recognized long before the present century, but it was Freud who chiefly brought the idea into prominence by using it to introduce into the explanation of behaviour emotional factors of which the subject is unaware. Freud himself and other psychologists have attributed to the unconscious a complex structure and dynamic functions; but these, as I have said, are not scientific concepts.

There are ways of looking at the unconscious mind which may provide a bridge between psychology and physiology, and which were to some extent envisaged by both Freud and Jung. If, as we saw earlier, emotion is to be regarded as an intrinsic part of the behaviour of the organism under the influence of its instinctive drives, it should not surprise us if feelings and impulses which are mediated by the most primitive part of the brain can sometimes move us without our being conscious of any rational explanation for them. Some psychologists believe that, by a process which is called conditioning, past experience may have operated to link together certain objects and certain feelings, although we can no longer remember the origin of their association, which may therefore now be described as unconscious. Man's very self-consciousness may entrap him when he seeks to explain his own or other people's behaviour if it encourages him to look for complete explanations in the conscious self.

Mind and the Social Environment

One of the characteristics of Western culture for many centuries has been the stress laid on the individual man. Whether the emphasis has been on human depravity, responsibility or perfectibility, or all three, the moulding influence of man's social environment on him has, until recently, been on the whole neglected. But if we neglect the individual's relationship with society, we shall not only fail to understand much of his behaviour, but also lose opportunities of influencing it. Only recently has man in society been studied scientifically by the social sciences; and what I have already said about the complexity of human behaviour will have shown how difficult this task is.

It has been pointed out[17] that we tend to enquire about causes only when we are confronted by some breach of routine. Thus we ask why a person is ill, and not why he is well. This tendency is exemplified in our attitude to social psychology, for it is when people behave in an abnormal manner that we call on sociologists to explain their behaviour, while we take for granted the behaviour of the large majority which presents us with no problem though this is of equal importance to the social psychologist and social anthropologist. Even a slight acquaintance with the literature of what has been called "social pathology" is enough to show the difficulties encountered by those who work in this field. Baroness Wootton[18] in her recent comprehensive monograph lists twelve hypotheses of separate factors believed to influence crime and delinquency. As she also points out, the relationship between anti-social behaviour and mental disorder, and indeed the concept of mental health itself, are the subjects of much confused thinking. For example, it is very difficult to define a psychopath, and to apply medical criteria to the legal concept of criminal responsibility.

As we have seen, the individual personality is the product of a number of factors: genetic ones may largely determine his intelligence and influence his psychological type, and he is exposed to a very complex and variable environment. How far are crime and delinquency determined by genetic factors? We must first bear in mind that, as Prof. L. S. Penrose[19] says, "crime is a relative phenomenon and it is measured by the standards of behaviour appropriate to a particular social system at a given time and place". In other words, it has meaning only in relation to the cultural environment. Penrose concludes that criminality is not a suitable trait for genetic studies except when it is associated with a clearly defined pathological condition. Genetic influences are probably important, but very little can be learned about their nature. We may conclude, therefore, that even when they exist, the most hopeful way to deal with them at present may be to discover what environmental factors activate them. A great deal of work is being done in the attempt to discover these, and there seems no doubt about the importance of family deprivations and social disturbances in the early years of childhood, but as the Gluecks[20], who have been working in this field in the United States for many years, say, "whether one looks at neighbourhoods or classes or cultures or sub-cultures, only certain individuals are chosen or choose themselves for careers of crime". Delinquent behaviour cannot therefore be put down solely to unwholesome environmental influences, which affect many people: it must also be attributed to individual lack of immunity to these influences. Both factors need to be taken into account. This is on the whole a hopeful view. "In delinquency", to quote the Gluecks again, "one is dealing not with destiny, but with destination, and destination can (hopefully) be altered." We clearly need much more knowledge, not only about individual reactions to environmental stresses, but also, more generally, about the normal emotional bonds between the individual and society. The social psychologist and anthropologist can help by comparing the features of very stable societies with those of changing cultures, and especially perhaps those in which, as in the developing countries, a previously stable society is rapidly exposed to new systems of ideas. It may well be relevant to consider not only the individual's emotional bonds with society but also the effect on him of the present view or conflict of views about the nature and purpose of life. We need, then, many more scientific observations over the whole range of human behaviour, normal and abnormal; but in science hypotheses too play an important part and in the social sciences we need fruitful hypotheses just as much.

Need for Extrapolation

Until man came on the scene, it was always the environment to which organisms were currently exposed that was important for them. Survival has never in the past depended on the conscious prediction of changes which had not yet occurred. Indeed, until man appeared, no animal possessed the power to do this, and even though man has profoundly modified his environment, and, incidentally, that of many other living creatures, his ability to predict the consequences of the changes he is producing has until recently been small. Even now, are we trying hard enough to foresee and prepare? As Prof. A. N. Whitehead[21] once put it, "a muddled state of mind is prevalent. The increased plasticity of the environment for mankind, resulting from the advances in scientific technology, is being construed in terms of habits of thought which find their justification in the theory of a fixed environment".

This truth has been overwhelmingly illustrated by the history of the thirty years which have passed since Whitehead wrote these words. The potentialities of science and technology for the benefit of mankind as a whole are almost inconceivably great; but the preparations which we are making for their use and development are pitiably small.

One of the outstanding examples of our failure to predict and prepare for the consequences of scientific development has been population growth. Now, thanks to the energy of a few people, chiefly in Great Britain and the United States, it is fairly generally recognized that there is a population problem, and that there is every prospect that the world population will have doubled from three thousand million to six thousand million by the year 2000. This of course is partly the result of widespread improvements in medicine and hygiene, and their life-saving consequences. The Food and Agriculture Organization's Third World Survey[22] shows that 10–15 per cent of the world's population are now living on a diet with insufficient calories, and 50 per cent are either undernourished or malnourished, or both. The task, not only of raising the standard of living for them, but also of providing such an improved standard of living for twice the present numbers in forty years, is the challenge which now faces us, and we must not forget that people need not only food, but also water, roads, industrial plant, education, and indeed all the means to a full life.

This is not a simple problem, nor is there any single solution. In some countries a larger population may be desirable: others will not be able to attain to a reasonable standard of living until they control their population growth. What is disturbing is that until now the human race has left its future numbers to chance. The average animal breeder has shown more concern about the consequences of his acts than the ordinary human being about what will happen to his own descendants. The animal breeder looks ten generations or more ahead; the human breeder not more than two, if that.

Great Britain has no population policy. The present rate of population growth took us by surprise, and we have not yet given thought to its implications. To take one instance from my own profession, it is clear that we shall need many more doctors in thirty years' time. This means more medical schools. It takes a minimum of 15 years to turn a first-year medical student into a consultant. Allowing ten years to build and equip a new medical school, we ought soon to begin to build the medical schools necessary to produce the consultants we shall need in the year 2000. Similar needs will arise in connexion with education, housing, roads and other necessities, and our existing road problems show how little we have prepared for what could have been foreseen. This is not a matter of obtaining more knowledge, but of persuading the Government to use the knowledge we have.

There is another aspect of the proper use of our resources which also urgently needs consideration. It is predicted that the progress of automation will leave many people with much more leisure. But automation will make little difference to doctors, midwives, nurses or school teachers. At present we have too few of all of these, and as the population increases, so will the shortage. Are we then to envisage a state of affairs in which the industrial part of our population enjoys compulsory leisure, while the professional part continues to be overworked? All that automation means is that fewer people are needed to do certain jobs. Should we not now be preparing for this by expanding the opportunities and incentives in medicine, nursing and teaching, to encourage more people to work in these fields? The benefits of automation would then be more evenly spread among those who work, and the community as a whole would benefit.

But world population growth cannot be dealt with adequately at national levels. We need an international body, sponsored by the United Nations Organization, to collect all available demographic information (and promote the search for it when it is not available), take into account present and prospective supplies of food and water, and the economic and cultural needs of growing populations, and review all present scientific work on population control. Every nation would then have the information on which to base its own population policy, and all would know what each was doing in a matter which collectively concerns us all.

Our greatest need to-day, then, is to acquire the power of looking ahead, forecasting, and preparing for the consequences of the accelerating developments in science and technology. Many years ago, H. G. Wells pointed out the need for what he called a "world brain" to correlate information and extrapolate it on the world scale, and I hope that one day we shall achieve something like that. But I can see only one main preliminary step towards all this essential foresight—education, and by education I mean education at all levels of society.

To my mind, the important division between people is not between the classical and scientific outlook on life, but between those who have been educated to see the world in terms of the rapidly changing environment, which science is creating, with all its potentialities, and those who see it in terms of the static environment, and frozen emotional attitudes of the past. The first group have to educate the second, which includes many of our rulers, as quickly as possible, and much encouraging work is being done on these lines, especially by international groups of scientists. But that, of course, is not enough. So far as we can, we must prepare all our people for a new world which will be quite unlike the old. This will mean spending more money and thought on education than we do at present, remembering that the best educational results are unlikely where home conditions are bad[23].

Education to-day has two tasks. First, it must concern itself with the whole individual, and therefore with behaviour. But here it must largely reflect the views and standards of society; and one of our needs as a society, now predominantly secular, is to develop a code of social responsibility which can form an integral part of education. Secondly, it must prepare people for leisure. Again taken by surprise, we find ourselves in a world in which many people have more leisure than ever before, and are at a loss to know what to do with it; and in a few years' time this problem will be much more acute. This is not only an educational problem, because the proper enjoyment of leisure, involving the re-creation of body and mind, calls for social facilities for which the State must largely be responsible.

Faced with these difficult educational tasks, we have one great new asset, which science has produced—broadcasting. Here is a means through which all who are willing can continue their education, and enjoy the arts throughout life, and which can bring to the attention of millions the issues which confront us. Broadcasting has re-created for the great modern democracies one of the conditions of the Greek city state: all citizens can hear and see their leaders, and a man need not even go into the market-place to hear the debates of the sophists: he can listen to them at home in his armchair.

I have left to the end the most difficult question of all. I asked earlier how far science can explain man? Many will say that science is a mode of knowledge which is concerned only with what is measurable, and that much of importance for mankind, including values, lies outside its scope. Science, it will be said, is ethically neutral, and the uses we make of it must be judged by standards of value arrived at independently. Others, however, will reply that human values themselves are the product of evolution, and survive only as fulfilling social and biological needs. Some difficult scientific and philosophical questions arise. Perhaps the most fundamental is this. Science uses symbols to denote events, and the relations between them. If there are events or relationships, human or otherwise, which cannot be adequately represented by scientific symbols, must not some aspects of them fall outside the scope of science? One of the difficulties of living in a time of rapid change like our own is that knowledge outstrips thought about it, but I feel sure that not all our present antinomies are permanent. We are learning every year more about the nature of matter, the relationships between events and the observer, between the brain and the mind, and between the living organism and its environment; and information theory may provide unifying concepts between the gene and the mind.

I started with the nervous system. Let me end by using it as an analogy. As individuals, we are all receptors, capable of supplying the higher centres with information. What information they get, therefore, depends on us. We are also the motor nerves, and what society does is done by us. But we are again, collectively, ourselves the higher centres, the forebrain, which mediates for the social mind the difficult task of receiving the information, learning from past experience, reacting to it emotionally, yet controlling its emotions; and, above all, looking to the future.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

THE SUN AND THE IONOSPHERE

THE subject of Mr. J. A. Ratcliffe's presidential address to Section A (Mathematics and Physics) is "The Sun and the Ionosphere". He directs attention to the fact that in recent years it has been possible to explore the upper portion of the ionosphere, above the peak of the *F* layer. This part has been called the 'topside' of the ionosphere. One of the most productive experiments makes use of an ionospheric sounder installed in an artificial satellite so that it sounds the ionosphere, downwards, from above. The principle is the same as that which is used in sounding from the ground; it consists in sending out short pulses of radio waves and measuring the time-interval before they return to the sender after reflexion at the ionosphere. The results are sent to the ground by telemetry. A very successful topside sounder of this kind has been made by workers in Canada.

In another experimental method, powerful waves are sent through the ionosphere on a frequency which will penetrate it completely, and the intensity, and spectral distribution, of waves scattered incoherently from it at different heights are measured. The electron distribution at still greater heights, out to distances of about five Earth radii, have been deduced from observations of a particular type of atmospheric called a 'whistler'. This results from the dispersion of the electro-magnetic pulse radiated by a lightning flash as it follows the lines of force of the Earth's magnetic field out to great distances.

The most distant parts of the ionosphere and the way in which it merges into the solar corona have been investigated by means of a space probe carrying a magnetometer. It has been found that the Earth's ionosphere merges into the Sun's ionosphere (the corona) at a distance of about ten to fourteen Earth radi[1]. Experiments of a different kind have been made in the first Anglo-American satellite, *Ariel I*, which carried experiments designed by workers in England. These experiments were designed to measure a series of quantities in the neighbourhood of the satellite. The concentration of the electrons, their temperature, and the masses of the positive ions which accompany them, were the quantities important for the present discussion. The density of the neutral atmosphere at these great heights has been deduced by observing how the orbits of satellites change as a result of the air resistance they experience in their motion.

The results from all these experiments provide information about the distribution in the outer ionosphere of the constituent gases, atomic oxygen, atomic hydrogen, and helium, and about the temperatures of the electrons, the ions, and the neutral gas. Theoretical explanations of the results involve consideration of how the energy of the photo electrons is transferred, first to the ions, and then from the ions to the neutral particles. Consideration of the rate of production of electrons, and of the rate of energy input, leads to suggestions about the incidence of energetic particles on the Earth's outer atmosphere.

CONTRIBUTION OF NEW INSTRUMENTS TO PROGRESS IN CHEMISTRY

DURING the past twenty years, the progress of chemistry has been dominated by the demand for, and the evaluation of, new techniques. This trend has been based to a very large extent on the development of new physical instruments and, if the present progress in this field is maintained, there are an infinite number of problems in chemistry which will be solved. Sir Harry Melville's presidential address to Section B (Chemistry) deals with the wider implications of instrument development and shows how progress in certain areas would have been impossible without the introduction of these new methods.

The often tedious chemical approach to the problems of measuring molecular weights has been completely superseded by the use of physical instruments. High-resolution mass spectrometry has enabled accurate determinations to be carried out in a matter of hours. The high-resolution electron microscope, for example, can be used to determine directly the weight of completely coiled high polymer molecules by measuring their diameter. Radioactive labelling is a method of micro-chemistry entirely dependent on instrumental techniques. In the field of polymer chemistry, where the weight of material being manipulated may be less than 10^{-7} g, it has put an end to many speculations about the course of chemical reactions occurring to minute amounts in high polymer systems.

The interaction of gases with solids has been investigated for years, but the preparation of uncontaminated surfaces has been a barrier to progress. The great improvement in vacuum pumps over the past few years has enabled this barrier to be surmounted, and clean uncontaminated surfaces can now be prepared and examined at leisure, using sensitive techniques such as mass spectrometry, gas/liquid chromatography, and electron field emission and ion emission techniques. The mechanism of homogeneous chemical reactions has yielded in many cases to complete analysis as the result of the development of new techniques. However, reactions which involve activated molecules, or which go through ionic or ion-pair mechanisms, have not yet yielded to these techniques, and here there is an enormous field for study.

Methods for tackling these problems are described. One involves the application of external stimuli to the system and observing the way it returns to the steady state. The problem is to devise equipment sufficiently sensitive to measure the small amounts of chemical change during the recovery period. The second method involves the application of electron spin resonance—here a considerable improvement in the sensitivity of present equipment is desirable. A third method involves the investigation of energy transfer in given systems. This involves the design of shock tubes and plasma-discharge apparatus, and the instrumentation to go with them.

These problems illustrate why a modern chemical laboratory is equipped in a very different way from ten or more years ago. The important point is that all the basic requirements of chemistry can now be carried out by more direct and sensitive methods. Increased sensitivity and greater resolving power of instruments are still very necessary and these depend on still further advances in physical techniques. To be effective, a modern laboratory must have this physical equipment, but the equipment must not be allowed to dominate the scene—the purpose of the equipment is to help the research worker to get on more quickly and precisely with his basic chemistry.

SOME ASPECTS OF EAST AFRICAN VULCANOLOGY

IN his presidential address to Section C (Geology), Mr. Wilcockson chooses to describe the Eastern, or Gregory, Rift Valley. This is a downfaulted trough extending from northern Kenya down to the latitude of Dodoma in Tanganyika. It is associated with minor structures on both sides. In the latitude of Nairobi, on the west side is the rift valley containing the Kavirondo Gulf of Lake Victoria and on the east, nearly opposite, a general fracture zone in which is situated the volcano Mt. Kenya. In northern Tanganyika, just south of the Kenya border, there is a similar pair of structures, on the west side the Eyasi Rift and the east side a fracture zone along which is a line of volcanoes culminating in Kilimanjaro. These crossings, as they may be termed, are the loci of intense volcanic activity.

On the west side of the southern crossing, the Eyasi Rift is filled with the eruptive products of the 'Giant Craters', a group of volcanoes mainly composed of alkaline lavas with little fragmental material and including the great Ngorongoro crater. In the nearby section of the rift valley are volcanoes, relatively recent in date, among which is the still active Oldonyo L'Engai. Among their outpourings are highly alkaline rocks associated with carbonatites, a type which has been reported recently as lava flows from Oldonyo L'Engai.

On the east side, Kilimanjaro has produced mainly lavas, but also some pyroclastics. Its early history is, of course, buried under later products, but the considerable proportion of the succession that can be seen shows a general change from trachybasaltic lavas to highly alkaline nepheline phonolites; the other volcanoes in this group contain similar rock types. One striking late feature is the presence of a very large number of parasitic cones which often show a reversal to basaltic types and ultra-basic crystal accumulates.

At the northern crossing the general course of events has been similar, though differing in detail. The volcanoes of the Kavirondo Gulf are alkaline in character and are associated with the intrusion of carbonatites. Mt. Kenya on the east contains phonolitic rocks, including the curious type kenyte, associated with basalts and an intrusive mass of nepheline syenite, while further to the east the Nyambeni Range is largely basaltic. Again, as on Kilimanjaro, the main activity is followed by a widespread parasitic episode.

In this latitude volcanoes associated with the rift-valley faulting poured out great floods of basaltic and phonolitic plateau lavas with some pyroclastics which cover enormous areas in the Aberdare Mountains and west of Nairobi. It is difficult to give any general succession of rock types for the whole region, but the early stages of the vulcanicity often seem to have been associated with the eruption of basaltic rocks which later gave place to more alkaline types, sometimes associated with carbonatites. In the rift valley west of Nairobi and elsewhere an acid trend developed resulting in quartz trachytes or even rhyolites.

The age of the vulcanicity has been the subject of much controversy. It is fairly certain that round the northern crossing the eruptions began in the lower Miocene while the outpouring of Kilimanjaro began on the end-Tertiary peneplain and much of its activity and that of the "Giant Craters" was of Pleistocene age.

ASPECTS OF MARINE FISHERIES RESEARCH

LARGELY owing to Government support, marine fisheries research has developed greatly since it was first a topic for an address to Section D (Zoology); hence it is appropriate that Dr. C. E. Lucas should review the present state of the subject in his presidential address to that Section at Southampton. Numbers and stock censuses are the very foundation of fisheries research and, during this time, their investigation has developed sufficiently to provide a theory of fish populations which is not only a basis for conservation and prediction but is also a major contribution to ecology. Yet, despite this and other developments, the seas and oceans are so vast, fish stocks extend and migrate over such distances, and marine processes (from water movements to productivity) are so complex that problems may increase as appreciation of them grows.

First, if the potential of the World's marine resources is to be exploited adequately, much greater knowledge of environmental influences is necessary. This has long been recognized but only recently has it become appreciated that equally necessary is a corresponding understanding of the behaviour and physiology of fishes, of their reactions to both natural and artificial stimuli. Nor are we here concerned only with the natural stocks and the natural conditions in which they come and go, and wax and wane. Such knowledge is, if possible, even more essential if the urge to cultivate the seas is to result in anything more than ill-considered, and consequently uneconomic, attempts to interfere with an exceedingly complex network of ecological interrelationships.

From the practical point of view, the problems facing marine scientists are not only fascinating and exciting, but also vital in terms of their potential contribution to the solution of increasing world food needs. Considerations such as these led, sixty years ago, to the foundation of the International Council for the Exploration of the Sea, under which the marine research resources of a number of nations have been increasingly co-ordinated over the years, to undertake investigations in the northern Atlantic which none could hope to solve alone. Its example has been followed by other groups, outside or within one or other of the fishery commissions which were later established to conserve marine resources; already various international projects have shown the inestimable value of collaboration in a field where events in one place may influence others more than a thousand miles away, and thus at one time may influence others much later in a complex space-time continuum.

In such a broad field, co-operation is essential at all levels, and especially between the 'pure' worker and the so-called 'applied' worker. Whenever a practical problem is anticipated the question is not 'how much time', or 'what resources' are necessary, but whether the essentially basic research has been done to be able to formulate the problem and its solution correctly. Thus a fair proportion of basic research is essential for a successful programme in a fisheries laboratory—and not only for this reason but also in order to attract to it workers of adequate calibre, who will never be satisfied solely with applying fundamental knowledge gained by others to the solution of practical problems which may lose their interest as soon as they are solved.

For such reasons, fundamental problems cannot be left to the academic laboratories alone. Not only does their specialization sometimes tend to isolate them from practical matters, but the broadly undirected nature of their work renders it chancy that they should contribute substantially to any immediate problems. Yet the resources of the fisheries laboratories alone are insufficient, despite the various special disciplines they now utilize, when faced with the vastness of natural processes on such an ever-varying scale. An important question, here as elsewhere, is how to encourage academic workers to devote rather more attention to those aspects of their investigations which could contribute to the solution of practical issues, without restricting unduly the freedom which is recognized as essential to the pursuit of understanding. The answer, here as elsewhere, seems to lie in an even closer association between the pure and the applied workers and laboratories. Applied research which is divorced from pure research is sterile indeed; perhaps pure research in its turn has some valuable stimulus to receive from the processes involved in applying research.

PLANNING AND THE GEOGRAPHY OF GREAT BRITAIN

THE subject of Mr. A. A. L. Caesar's presidential address to Section E (Geography) is "Planning and Geography in Great Britain". The need for planning on the city scale is now generally appreciated. There is also a gradually increasing awareness of the significance of wider relationships and the need to plan on the regional scale; but there is still very little appreciation of relationships on the national scale and of the profound changes in values, with changing techniques, inherent in the geography of Great Britain as a whole. Changes in techniques since 1918 have been many and varied, two main groupings being dominant—changes in the industrial and occupational structures and distributions, and the 'revolution' in transport.

The First World War produced marked and sudden changes in the economy of Great Britain. Consequential changes in the distribution of industry generally between the Wars were frequently described as 'the drift to the South', but this is an inaccurate description. The overall problem was not a contest between North and South, but between a declining periphery and a growing centre.

The effects of new developments in transport for both passengers and freight, and particularly the coming of modern road transport, did much to enhance the contrasts between the periphery and the centre. In absolute terms, the periphery is much more accessible than it was, but in relative terms it is less so and it is the relative relationships which are so important.

Since the Second World War, Great Britain has experienced near 'full employment' in marked contrast to the heavy unemployment of the inter-war years. Nevertheless, problem areas have presented themselves, and all the Development Areas or 'Development Areas Treasury Advisory Committee' areas are on the periphery. National circumstances have changed markedly, but the contrasts between the periphery and the centre persist. They have

ANALYTICAL METHODS FOR PESTICIDES, PLANT GROWTH REGULATORS, AND FOOD ADDITIVES

Edited by **Gunter Zweig**

***Special subscription price valid until October 31, 1964**

Volume 1: **Principles, Methods, and General Applications**
Z906 1963, 637 pp., 171s. 6d. Z905 **Subscription price 150s.***

Volume 2: **Insecticides**
Z910 1964, 619 pp., 164s. 6d. Z909 **Subscription price 143s.***

Volume 3: **Fungicides, Nematocides, Soil Fumigants, Rodenticides, and Food and Feed Additives**
Z914 1964, 237 pp., 86s. Z913 **Subscription price 80s.***

Volume 4: **Herbicides**
Z918 1964, 269 pp., 86s. Z917 **Subscription price 80s.**

Special features . . .

- designed to provide research chemists in industry, universities, and the government, especially those interested in the analysis of these chemicals in relation to environmental health, with a single comprehensive information source on the subject.
- provides detailed coverage of such recent methods as gas chromatography–electron capture, neutron activation analysis, and spectrophotometric techniques in their applications to pesticide and food additive research.
- describes apparatus and chemicals in detail.
- presents procedures described by the originator of the method, or a recognized expert in its use.

SILICATE SCIENCE

By **Wilhelm Eitel**

***Subscription prices are valid on orders for the complete set placed prior to publication of the last volume**

Volume 1: **Silicate Structures**
E460 September 1964, 666 pp., 171s. 6d.
E461 **Subscription price 150s.***

Volume 2: **Glasses, Enamels, Slags**
E462 November 1964, 704 pp.

Volume 3: **Dry Silicate Systems**
In preparation

Volume 4: **Hydrothermal Silicate Systems**
In preparation

Volume 5: **Ceramics and Hydraulic Binders**
In preparation

This treatise will provide investigators in silicate science with information on the basic chemistry of silicates, and their natural and industrial significance in glass, ceramic, and construction material practice.

THE LIVER

Morphology, Biochemistry, Physiology

Edited by **Ch. Rouiller**

R690 Volume 1, 1963, 683 pp., 186s.
R692 Volume 2, 1964, 674 pp., 171s. 6d.

In writing this treatise, the authors offer in a comprehensive form the present state of knowledge of the liver as based on morphological, biochemical, and physiological studies. The areas of greatest emphasis include a correlation of structural, functional, and biochemical aspects, recent findings established through modern methods of investigation, and experimental studies with animals of pathological changes in the liver.

JUST PUBLISHED
ACADEMIC PAPERBACKS

BIOLOGY

Design and Function at the Threshold of Life: The Viruses
By Heinz Fraenkel-Conrat
X850, 117 pp., 15s. 6d.
X851, clothbound, 39s. 6d.
Review: "... one of the very few authoritative books that can bridge the gulf between the scientist and the humanist with depth and substance ... a source of information and inspiration."—*Science.*

Time, Cells and Aging
By Bernard L. Strehler
X770, 270 pp., 23s.
X771, clothbound, 40s.
Review: "This is one of the best available accounts of the present state of research on fundamental causes of ageing . . . highly important background material for physicians and biologists alike."—*The Lancet.*

Isotopes in Biology
By George Wolf
X960, about 175 pp., 17s. 6d.
X961, clothbound, 39s. 6d.
●treats the related aspects of isotope usage—methods, units, health hazards, principles and applications, and rates of reactions in living systems.

PHYSICS

Crystals
Their Role in Nature and Science
By Charles Bunn
X160, 286 pp., 24s. 6d.
X161, clothbound, 46s. 6d.
Explanation is given of crystalline form and manner of growth, and the contributions furnished by this knowledge to our understanding of light, x-rays and the structure of solid substance.

Elementary Dynamics of Particles
By H. W. Harkness
X400, 219 pp., 21s.
X401, clothbound, 43s.
●a thorough survey of basic particle dynamics for the physics and engineering student.

Elementary Plane Rigid Dynamics
By H. W. Harkness
X404, 197 pp., 21s.
X405, clothbound, 43s.
Among the topics covered are gravitational potential, friction, and waves in quasi-elastic and elastic media.

Potential Barriers in Semiconductors
By B. R. Gossick
X350, about 150 pp., 17s. 6d.
X351, clothbound, 39s. 6d.
The potential barrier in a semiconductor, and the electronic processes which occur within and outside the barrier are thoroughly explained.

Mössbauer Effect
Principles and Applications
By Gunther K. Wertheim
X930, 116 pp., 17s. 6d.
X931, clothbound, 39s. 6d.
The concept of recoil-less resonant scattering of nuclear gamma rays in solids has made possible experiments only dreamed of before Dr. Mössbauer promulgated it.

MATHEMATICS

Elements of Abstract Harmonic Analysis
By George Bachman
X150, about 275 pp., 24s. 6d.
X151, clothbound, 46s. 6d.
●includes topological spaces, classical Fourier analysis, Branch algebra, Haar measure, and compact Abelian groups.

Introduction to *p*-Adic Numbers and Valuation Theory
By George Bachman
X154, 173 pp., 24s. 6d.
X155, clothbound, 46s. 6d.
Basic algebraic notion of valuation on a field is joined with the number-theoretic concept of the *p*-adic fields.

Noneuclidean Geometry
By Herbert Meschkowski
X500, about 125 pp., 17s. 6d.
X501, clothbound, 39s. 6d.
The text's short format will enable the student to quickly deal with automorphic functions, the theory of discontinuous groups, and the uniformisation of algebraic functions.

Finite Permutation Groups
By Helmut Wielandt
X950, 114 pp., 17s. 6d.
X951, clothbound, 39s. 6d.
The author collects in this volume the basic theorems on permutation groups.

Quadratic Forms and Matrices
An Introductory Approach
By N. V. Yefimov
X970, about 175 pp., 17s. 6d.
X971, clothbound, 39s. 6d.
●focuses principally on problems concerning conics, quadrics, and geometric interpretation.

been further emphasized by many developments of the past twenty years. Analysis of the likely effects of the new road bridges and tunnels of the major estuaries, of the layout of the 275-kV grid, of the proposals of the Beeching Report, of access to commercial services and many other features, all show that the periphery is at an ever-greater comparative disadvantage.

Great Britain's problem is the concentration of urban functions and much economic activity. This problem is common to many parts of the world, but it presents particular difficulties and greater urgency in this small, irregular and densely-peopled island. To think of present planning problems simply as the rapid relative growth of the South-east at the expense of other regions is to think in the wrong terms. Great Britain must face the coming of 'Megalopolis'—the vast diffused city which will occupy much of the Midlands of England with dormitories on the nearer coastal areas particularly in the South-east. The days of planning separate cities and towns, and possibly of local government areas as now known, have gone. The planning of 'Megalopolis' requires the biggest minds and a carefully controlled imagination—personnel will be difficult to find. One thing at least is clear—it must be planned with a full appreciation of the profound and continuing changes in geographical values. Given the changes in spatial relationships of recent years thinking even on a regional scale is not big enough, and we must take cognizance of the geography of Great Britain as a whole.

ENGINEERS AT THE CROSS-ROADS

TO-DAY engineers in Britain are facing a new dilemma —the dilemma of professionalism. The problem as Mr. H. G. Conway sees it in his presidential address to Section G (Engineering) is: do engineers want to become 'respectable', raising the title 'engineer' above the level of a garage mechanic? Moreover, what is Britain's greatest need: for scientists to advance the boundaries of technology, or for engineers to apply its fruits? In many fields, remarkable engineers are found who have had little or no technical education. These men, the Henry Royces of to-day, succeed because an instinctive ability, particularly in design, cannot be held back by a lack of formal qualifications. In science, however, academic training is more necessary, and there is perhaps less scope for intuitive genius without academic embellishment. Many professions, such as medicine and the law, require strict compliance with the rules of the profession if success is to be achieved.

While comparisons between engineers and scientists can be made (but tend to be very inaccurate), one common factor is that the successful individual in either discipline tends to have an intelligence well above the average of the community. That there are certain essential differences within each group can broadly be related to an interest in the practical or in the abstract. It is essential that these differences are kept in mind when educational patterns are directed towards the future needs of technology. Obviously too rigid an educational system might hamper the progress of some men, and this is particularly true of the visually perceptive and mechanically apt men who may not be so successful in passing through the normal university degree course.

Intelligence is a quality that many men have. However, the knack of making use of it is another quality. Psychologists in the United States, investigating the difference between creativity and intelligence, have shown that the conventional intelligence quotient rating system leaves much to be desired in assessing those qualities which comprise creativity. Indeed they give some evidence indicating that young people of high intelligence (by *I.Q.* rating) are generally low in creativity. Perhaps here is the essence of the differences between the scientist and the engineer. While the average scientist would probably be proud to have a high *I.Q.* rating, and certainly gifted, highly intelligent children are most likely to be able to follow the educational stream which produces scientists, in some branches of technology, virtually throughout engineering, creativity is highly important. It is common experience that those who do best have some innate ability which is not necessarily nurtured by a university curriculum.

Traditionally, the ambition of the British parent is for his child to go into a 'respectable' profession, such as medicine, law or finance. It is only recently that science and technology have become recognized as 'respectable' professions. It can be questioned whether steps are being deliberately taken to raise the professional status of engineers, so that they have the same public standing as doctors, dentists, accountants, etc. A generation ago the engineer would join a learned society because he was interested in his new profession and wanted to keep up to date, 'in the swim', by means of its journal. Meetings were only attended occasionally, branches outside London being few. There were no ties to wear symbolically! The young engineer of to-day is much the same as his father, except that competition is far keener and technology vastly more complex. Specialists have brought about the setting up of artificial barriers within this creative discipline, and now it is necessary to distinguish between electrical and mechanical engineering, etc. It is clear, however, that a method must be found for rating qualified engineers in such a way that the general public will know them for what they are.

A step forward in this endeavour was made in 1963 when the Engineering Joint Council was formed. Hereby a means was established for thirteen learned societies to set common standards which will enable the 'professional engineer' to be given a good standard without reference to whether he is electrical, mechanical, chemical, etc. The problems of standard are immense, and in no circumstances can a lowering of any standard be tolerated. Certainly the Joint Council must set a standard which will be equivalent to a university degree, and it must lay down the standards of professional experience which must also be achieved before the young member of a constituent institution can be allowed to call himself a 'professional engineer'.

HISTORY AND ARCHÆOLOGY

THE rapid expansion of British archæology in the late nineteenth and early twentieth centuries was largely concerned with prehistory and was carried out in close association with the natural sciences. As a consequence, the link with historical studies, which had always been realized in the field of Roman Britain, became dangerously weakened in other branches of British archæology. The necessity for re-examining the relations between historical and archæological studies has become increasingly evident as medieval and post-medieval archæology have grown in stature in the past generation. It is thus fitting that Dr. C. A. Ralegh Radford should choose

"History and Archæology" for the subject of his presidential address to Section H (Anthropology).

Until the margin of error in scientific dating by carbon-14 or other methods becomes substantially less than at present, the traditional archæological methods of dating by association will continue to form the basic element in establishing the chronology of later prehistoric ages. These methods rest ultimately on historical data, and their successful application demands an understanding of these data. For the same ages the written record provides isolated pieces of information, which, rightly used, enable the student to fill out and bring to life the picture built up by the scientific analysis of data afforded by archæological investigation, which must continue to form the basis of any reconstruction. An example from British and Gaulish protohistory is provided by Cæsar's account of the equities. This dominant secular class in Gaulish society should certainly be associated with the rich *La Tène* burials of Britain and the Continent and probably with the great contemporary farmhouses of the Little Woodbury type. The fortunes of this class can be followed into the Roman period, when a connexion between these farmhouses and the villas is beginning to emerge.

In the later prehistoric and Roman ages the written record concerned with Britain consists of isolated references by distant writers, whose main interests lay elsewhere. With the coming of Christianity in the seventh century, the evidence of native writers and documents becomes increasingly available and historical studies gradually become dominant.

Instances where the written record of a particular site or building can be directly tested by archæological methods are rare. Hexham, which might have become a text-book example, is rendered difficult by the obscurities of the texts and the inadequacy of the excavations. Winchester, where a large-scale investigation is in progress, may afford more useful results.

But real collaboration between historical and archæological research must rest on a wider basis. The picture obtained by the analysis of the whole range of historical material must be tested by field research and by the excavation of key sites. These sites must be regarded as historical and sociological documents. In pre-Conquest England the towns—especially the late Saxon burghs—and the dwelling-houses provide suitable fields for investigation.

BIOCHEMISTRY OF THE ENDOCRINE SYSTEM

THE biochemistry of the endocrine system forms the subject of Prof. F. G. Young's presidential address to Section I (Physiology). Although the idea that certain glands may provide internal secretions, liberated directly into the blood stream, is sometimes ascribed to Claude Bernard, the belief that glands which do not possess a secretory duct may discharge useful material directly into the blood seems to have been generally current during the 1840's. The important observations of Thomas Addison about the effects of disease of the adrenal glands (1849, 1855), and of A. A. Berthold (1849) concerning the endocrine activity of the testes, may well have been influenced by general contemporary ideas about internal secretion before Bernard's observations concerning the secretion of glucose by the liver (1853).

Many hormones are concerned in the control of the movement of materials across barriers. In many instances endocrine glands are themselves derived from tissues which, at one stage in evolutionary and embryological development, constituted a part of a barrier tissue between the external and internal environments of an animal. This may be significant with respect to the evolutionary development of what are now called 'hormones'. Hormones may be metabolites to which responsive tissues concerned with transport have been evolved and the production of which became largely, though not entirely, confined to one tissue.

In some instances two hormones may act on the same process in such a manner that under the influence of one hormone the process is intensified while under the influence of the other the process is depressed. Such an antagonism between the action of hormones can be of particular physiological significance, and is well illustrated by the actions of insulin and of pituitary growth hormone. Under the influence of growth hormone there is a tendency for the blood sugar to rise, and for the amount of albumin-bound fatty acid in the plasma to rise also. These two actions are the converse of those of insulin. The action of growth hormone probably prevents the development of post-prandial hypoglycæmia and an excessive fall of plasma-free fatty acids, and conserves amino-acids, while insulin provides a means of preventing an excessive rise of these constituents of the blood after a mixed meal. In simple terms, insulin is the hormone of plethora while growth hormone is that of scarcity. Antagonism between their actions can provide for balanced metabolic control. Growth may result when the metabolic pattern normally associated with scarcity is imposed on conditions of plethora.

BIOLOGICAL BASIS OF CRIMINAL BEHAVIOUR

PROF. H. J. EYSENCK reminds us at the opening of his presidential address to Section J (Psychology) that constitutional views about the causation of crime were widely accepted at the turn of the century; they have been superseded by views stressing environmental causes. It would seem that the pendulum has swung too far over in this direction; man is a biological organism as well as a social one, and it would seem that the time has come for a re-awakening of interest in the biological causes of criminality. The facts certainly leave little doubt about the importance of constitutional factors; following the work of Lange, many other investigators have demonstrated that when criminals with identical sex brothers or sisters are singled out in prison the concordance rate of their twins is more than twice as much when they are identical than when they are fraternal. Along similar lines it has been shown that the personality make-up of criminals combines high emotionality with a high degree of extraversion, as contrasted, for example, with neurotics who tend to combine high emotionality with high degrees of introversion. Both emotionality and extraversion/introversion have been shown in many different studies to be markedly influenced by hereditary factors. Most of these facts have been known for a long time; the main reason for disregarding them has usually been the difficulty of seeing how biological factors could influence conduct classified on ethical or social grounds. What is inherited can only be structure, not behaviour, and no clear theory existed relating the one to the other.

In recent years it has been suggested that there is a close relationship between extraversion/introversion on one hand, and cortical excitation as opposed to cortical inhibition on the other. These terms refer to facilitation or its opposite in relation to cortical activity, and it is likely that there is a close relation between excitation and the activating part of the reticular formation, and inhibition and the recruiting or synchronizing part. It may be deduced from this hypothesis that introverts form conditioned reflexes better than extraverts, and much evidence exists to show that this is indeed so. Given then that extraverts and introverts differ with respect to the ease with which conditioned reflexes are formed, we may here have the necessary link between structure and behaviour. More specifically, Prof. Eysenck suggests: (1) that neurotic reactions are conditioned autonomic reflexes, or the skeletal or hormonal reactions thereto; (2) that criminal activity is facilitated or brought about by the absence of conditioned autonomic responses to the contemplation and execution of socially undesirable actions which are subjectively experienced as 'conscience'. According to this theory, the new-born child's conduct is completely asocial or 'criminal'; in order to learn a socialized mode of behaviour, a lengthy process of conditioning is necessary in which certain types of activity labelled 'bad', 'naughty' or 'wicked' are immediately followed by some form of punishment. This punishment acts as the unconditioned stimulus, and by virtue of its contiguity becomes associated with the conditioned stimulus, that is, the contemplation or carrying out of the forbidden activity. Gradually the conditioned stimulus will acquire the power of producing the same response as the unconditioned stimulus, that is to say, sympathetic arousal, anxiety, fear, etc., thus acting as a deterrent from any asocial activity. The whole process is aided very much by the labelling of all such activities by parents, teachers and peers; in this way stimulus generalization occurs, and unifies and extends the whole field of forbidden activity.

It will be clear that in this process extraverts, who condition poorly, are handicapped and will acquire a well-established 'conscience' only with difficulty, whereas introverts will condition only too well and be plagued by guilt feelings, even where the average person would consider such guilt feeling inappropriate. These genetically determined factors interact with the environment, which provides the conditions of reinforcement, and variations in these prevent the correlation between conditioning and criminality from being perfect. It is suggested that from the point of view of prophylaxis and treatment, individual differences in rate of conditioning must be taken into account and that ways and means must be found to make use of the accumulated knowledge of psychologists regarding the establishment and extinction of conditioned responses. It is possible, for example, to increase the conditionability of a person by the administration of stimulant drugs; it is possible to prevent extinction to a large extent by partial reinforcement, and there are many other ways in which behaviour can be manipulated so as to avoid criminal behaviour or reclaim the criminal. All such activities to be successful must, however, rest on a proper scientific analysis of the problem and a recognition of the importance of innate individual differences, particularly in the rate of conditioning.

FUNGAL FRIENDS AND FOES

"FUNGAL FRIENDS AND FOES" is the title of Prof. C. G. C. Chesters's presidential address to Section K (Botany). Fungi are part of man's normal environment and are vital for the circulation of carbon, nitrogen and minerals in Nature. They become important in man's economy because they depend on organized sources of carbon for their own synthetic processes and energy supplies. Throughout time man has engaged in the monoculture of food crops and, in so doing, has provided phytopathogenic fungi with an assemblage of hosts which they have continually exploited. The ability of such pathogens to develop new strains and the wide distribution of mixed populations of pathogenic strains requires the continual vigilance of mankind, and a never-ceasing attempt to find more effective means of prevention and control.

Animals, as well as plants, represent food sources for fungi, and many of them cause serious diseases in animals. Some depend on animals for their dispersal and others are closely knit with the life-cycles of insects. This is a feature of ambrosia beetles. In certain insects, digestion of their food and perhaps their vitamin requirements depend on fungi and bacteria located in their digestive tracts.

While pathogenic fungi continually menace food crops, saprophytic fungi cause spoilage of many of the essentials of man's livelihood. Heart-rot of standing trees only differs in degree from moulding of stored food products and textiles. The natural versatility of fungi, their wide battery of enzymes, the profusion of spore production, and the efficiency of spore dispersal are factors which enhance their nuisance value.

However, these same characteristics make them useful to mankind when they are cultivated on sterile media. The vast array of syntheses of which they are capable and the ingenuity of the chemical engineer have placed at man's disposal not only antibiotics, but also a wide range of organic acids, enzymes, vitamins, proteins, amino-acids, and other carbon compounds. The exploitation of fungi is only limited by the costs of operations, but the combined skills of mycologists, chemists, and engineers should open wider fields of usefulness, particularly in a world facing the necessity of finding new sources of food materials.

Underlying all their destructive propensities, and their usefulness to mankind, lies one very simple feature: fungi lack chlorophyll and are entirely dependent on organized sources of carbon for their existence.

NEED FOR FORESTS IN AN INDUSTRIAL SOCIETY

EVER since early man began to develop a communal existence he has tended to slaughter his forests to make room for other land uses or to safeguard himself from enemies sheltering therein. In Britain this process had advanced far at the period when she began to take possession of overseas colonies, whereupon her rapid industrialization made tremendous calls on the newly discovered timber reserves overseas. Belatedly, skilled forest conservation has endeavoured to ensure the safety of future supplies.

To-day Western Europe as a whole is a gross importer of timber and timber products, and Britain is dependent on overseas supplies to the extent of 90 per cent of her needs. Only recently have most countries begun scientifically to look ahead to their long-term industrial, social and domestic planning; in doing so it begins to be possible to foresee how timber resources will need to be conserved or increased in relation to the known world availability and world requirements. The picture is far from rosy, but with increased knowledge of the cultivation and use of fast-growing species immediate action can be expected to safeguard the situation. The aim of Mr. G. B. Ryle's presidential address to Section K* (Forestry) is to express some general thoughts as a challenge to our sense of urgency.

The British forest policy, hitherto based largely on the need to build up a reserve of growing timber as a safeguard in the event of another war, has now moved towards the need to maintain and increase forest production for economic and social reasons, to ensure the improvement of conditions in the poorer upland areas where grazing husbandry is failing to support a modern educated population and to improve the broad use of rural land also for the recreational benefit of the people as a whole.

The development of high-production forestry since 1919 is already creating an intense interest among industrialists, and as more supplies of the raw material become available so the building of new wood pulp factories, particle board mills and sawmills is following. As Mr. Ryle points out, the forest has much to offer to an industrial society in addition to its direct provision of an industrial product. By a close collaboration with the National Parks Commission and the Nature Conservancy so the forest is providing additional recreational facilities and opportunities for biological study equal to their national parks and their nature reserves.

The forest in a highly populated country must not be managed simply as a timber-producing factory. It is a storehouse of industrial wealth, of animal and plant communities and a place for recreation for the townsman. It is hoped that the townsman will collaborate to preserve this growing heritage.

RESPONSIBILITY AND EDUCATION

THIS year, half-way between the optimism of the Education Act of 1944 and the pessimism of Orwell's "1984", the Education Section (L) of the British Association has resolved to pass in review some of the major issues of responsibility in education. In his presidential address to this Section, Dr. F. Lincoln Ralphs attempts to indicate some of the broad issues involved and to set the stage for subsequent papers on the responsibility in education of the State, the Press, teachers, parents, etc.

Education and responsibility are held to be as inseparable as the obverse and reverse faces of a coin. By them *Homo sapiens* buys his right to a status unique among the animals. The educative potential of the totality of human environment must be recognized and our failure to accept responsibility in this context leads to a confusion of education with schooling and with erudition. It has led to a dichotomy between the standards advocated in school and accepted by Society. It may be there is a present preoccupation with truth at the expense of some neglect of beauty and goodness, a neglect that is excused as a revolt against hypocrisy.

Against this background the religious clauses of the 1944 Act reflect not only an attempt to reconcile the education provisions of the State and the Church but also the manifestation of war-time faith and fears in marked contrast to the present climate of thinking. There is at the present time an emphasis, even an over-emphasis, on scientific method and measurement as the only acceptable form of enquiry. Dr. Lincoln Ralphs considers that this produces a quantitative rather than a qualitative concept and is reflected in a change of emphasis from excellence and perfection to the average and the normal.

The present rapidly changing pattern of education contrasts markedly with the broad philosophy of education which had developed in the nineteenth century. "To the needs of this tranquil, stable but steadily evolving society the education and responsibility of the three R's ministered with servile conformity. Parents were as much concerned to enquire about their children's conduct as their competence. Integrity was rated as high as intellect. Manners still made man. Then, in 1914, the smouldering embers of the Balkans caught fire at Sarajevo and the world was at war. Solid structures of the past softened and melted in the new, accelerated way of life. The stage was being set for a new standard of values." The privileges of a minority in the nineteenth century became demanded as the rights of all in the twentieth, but this standardization, rationalization and certification are not necessarily the best guarantees for educational advance. "Large classes and increasing emphasis on factual knowledge which examinations tend to encourage are not calculated to inspire pupils to accept responsibility either for themselves or for others."

The responsibility of parents is basic. Their training to meet the responsibility is minimal. If the education problem begins in the home its ultimate extension is world-wide and its responsibility cannot be circumscribed in any parochial fashion. "A brain drain may be necessary if we are to deal with the effluent of ignorance that a divided world has left to poison society with prejudice and violence." In a final analysis of responsibility and education it is impossible to escape the conclusion that the central theme depends on the concept of the nature of man. "Our origins may be seen from the stern of the *Beagle*. Our destiny is not decided in its wake but in our own consequent involvement in the conflict of good and evil and our growing recognition of what is true and what is not true. . . . If we offer human nature as an excuse for what we no longer hope to perfect we return to the dust."

THE AGE OF ADVICE

PROBABLY the earliest record of science being called to the aid of agriculture is contained in the writings of John Milton the poet to Samuel Hartlib in 1651. The recommendations of other writers in the seventeenth and eighteenth centuries and the activities of the Brecknockshire and other agricultural societies from 1755 onwards undoubtedly led informed public opinion to support the private endowment of the first chair of agriculture in the University of Edinburgh in 1790.

Subsequent development, as Mr. Eric Rea points out in his presidential address to Section M (Agriculture), was slow and spasmodic with a pronounced active period in the decade around 1840 which saw the inauguration of the Royal Agricultural Society of England, Rothamsted, the agricultural colleges at Cirencester and Glasnevin, and further chairs of agriculture at Oxford, Aberdeen and Belfast. The last thirty years of the nineteenth century saw the foundation of a number of small colleges and teaching institutes—many of them now defunct—and a trio of significant events in 1889; namely, the County Councils Act; the Technical Instruction Act and the founding of the Board of Agriculture. By this means, Government funds and support were available on a modest scale and for the first time.

The Development Act of 1910 provided the next stimulus to county councils and universities, who co-operated and laid the foundations of the nation-wide system of agricultural education and advice developed between the two World Wars. The interruption of the Second World War provided the opportunity for a systematic review by the Luxmoore Committee, whose report led to the setting up of the present National Agricultural Advisory Service within the Ministry of Agriculture. Farm institutes and extra-mural activities were left with the county councils and the Ministry of Education.

The new unified service offered equal farmer facilities in all parts of England and Wales and improved service conditions and career prospects. Formed in 1946 when siege conditions had barely eased, the new service had a difficult start, but within ten years the developed world—aided by an unparalleled scientific revolution—was moving into an era of plenty. Scarcity gave way to plenty—even to food surpluses—and to keen international competition. Scientists produced new concentrated, friable fertilizers to exploit the potential of high-yielding stiff-strawed cereal varieties, selective herbicides to increase yields and reduce cultivation costs and a profusion of mechanical equipment to supply cheaper power and reduce labour requirements.

Livestock numbers and production efficiency show marked increase and farm output has nearly doubled compared with pre-war despite a decline of more than 20 per cent in farm workers. The total cereal acreage in South-east England has doubled since 1939. Wheat is a little above pre-war, oats show a sharp decline and there has been a nearly universal swing to barley in defiance of rotations and of the previously accepted husbandry code.

The effects of economic pressure have been felt most severely on small farms which lack the advantage of scale and rely heavily on livestock, which provides 70 per cent of the national farm income. This situation has been countered by the advisory service developing widespread economic or farm business management advice with the co-operation of the university departments. Simple enterprise costings have tackled feed costs, which loom large in livestock production, and more sophisticated whole-farm business analysis has been developed. Thus the major factor in doubling farm output and in lowering production costs has been the impact of the advancement of science brought to the farmer by Government-sponsored research and advice.

Changes in consumer demand in an affluent society are reflected in modified streamlined production patterns and simpler farming systems. Important developments in marketing are in progress. In the future, development will continue, but whatever form it takes there is every indication that farmers will depend heavily on unbiased scientific guidance in this, the "Age of Advice".

HOW SMALL-SCALE SOCIETIES CHANGE

IN her presidential address to Section N (Sociology), Dr. Lucy Mair suggests that when problems of social change are discussed it is often assumed that change in itself needs to be accounted for. Analyses of society in terms of structure and of socially approved behaviour in terms of roles have been called deterministic. Studies of the relation between culture and personality can result in a picture of society in which everyone's behaviour has been fixed by his or her upbringing in so rigid a mould that any change from established patterns calls for an explanatory theory.

Our nineteenth-century predecessors would have been astonished at the idea that social change as such presented a problem. In fact, it has become the subject of interest in the special form that it takes in this century, where the technical inventions of the Western World are being introduced to societies the indigenous technology of which is very simple.

It is suggested that the social changes resulting from this can be best understood if we recognize that a field of free choice is open to the members of any society, although the field is narrower where the level of technique is lower and the total field of social relationships narrower. The choices that men make are directed to comparable ends in all societies. They pursue wealth, power and the esteem of their fellows. These ends may be incompatible; people may have to choose between material advantage, increase of power, and the esteem given to those who respect their obligations.

In social terms, the entry of the newer States into the world economy has widened the range of opportunities open to individuals. They choose whether to enter into new types of relationship by balancing the advantages that these offer against the cost in loss of esteem through their neglect of pre-existing obligations. The conservatives are either the unimaginative or those who have more to gain by keeping to the *status quo*.

With the attainment of independence, these countries have rejected the claim of Europeans to tell them how they should take on the roles required by the social structure of a modern nation. In Africa they say that such roles must be so interpreted as to express the 'African personality'. This applies particularly to the field of politics, where the characteristic departures from Western ideals of democracy are explained in terms of traditional African customs and values. But a preferable explanation is that persons taking on political roles in the new states find themselves in an open situation in which they can themselves create their roles. These men are drawn from a different stratum of society from the traditional rulers, and are not seeking to follow tradition, but to work out for themselves the means of attaining and holding power. They interpret the new political roles in the manner which seems to them most apt for these aims, and there can be no effective challenge to this interpretation in the present social structure of their societies.

Contemporary social changes, like social change in the past, is produced by the manipulation of whatever areas of free choice there may be by people who are able to calculate where their advantage lies.

RESURGENCE OF INTEREST IN THE OBSERVATIONAL SCIENCES

IN his address to Section X (General), Sir Graham Sutton contrasts the progress in the observational (or environmental) physical disciplines with that in the experimental (or laboratory) physical sciences. In the observational sciences, naturally occurring uncontrolled events are investigated, usually on a synoptic basis, whereas in experimental physics controlled events are created and investigated, so far as possible, in isolation from other events. The two branches have a common foundation in the universal laws and principles of theoretical physics.

Much of early Western science was observational, usually with astronomical events as its basis, for at that time there was an almost complete lack of reliable laboratory data. Newtonian mechanics is often represented as a breakaway from the teleological science of Aristotle; but Newton himself seems to have been influenced by a desire to explain natural events as part of a universal order instituted by the Creator. It was not until some hundreds of years later that the growing skill of the instrument-maker and the emergence of the modern laboratory made it possible to extend the study of the universe by man-made events and laboratory artefacts.

The handicaps suffered by the environmental physical disciplines are well illustrated by meteorology, which for centuries could not advance significantly until the telegraph provided a rapid and certain means of building up the synoptic picture and ways had been found to explore the upper atmosphere. Modern meteorology began to take shape when advances in electronics produced the radiosonde, the radar wind-finder and finally the high-speed computer.

To-day the environmental physical sciences have been rejuvenated by technical developments. They demand a wide-ranging knowledge of physics, as exemplified by modern geomagnetism, which began in the seventeenth century with a study of variations in magnetic compass directions and now extends from the inner parts of the Earth to the fringes of its outer atmosphere, involving subjects as remote as the study of convection currents in the molten interior of the Earth to the physics of charged particles emanating from the Sun. It has also led to the examination of conditions in the remote past, with links with the drift of continents and palæoclimates.

The most exciting possibility in the Earth sciences to-day is that of modifying or even controlling weather. Examination of the orders of magnitudes suggests that little can be achieved by a direct contest with Nature, but that something might be possible by more subtle means. This requires, however, a much more detailed knowledge of large-scale atmospheric processes than is available now, and the conclusion is reached that the most that should be attempted at present is the investigation of model atmospheres with the help of computers. Any large-scale effort in the real atmosphere might have disastrous consequences.

THE SOUTHAMPTON REGION

A Survey of Southampton and Its Region

Edited by Prof. F. J. Monkhouse. Pp. xviii + 349 + 56 plates. (Southampton : The University Press, 1964. Published for the Southampton Local General Committee of the British Association.) 35*s*.; 5 dollars.

THE first impression gained of *A Survey of Southampton and Its Region* is that in the area they—the inhabitants—obviously take things rather seriously, especially their own extremely beautiful 'Wessex'. The book has all the appearances of being rather academic, with many detailed tables, maps, intricate graphs and diagrams. Is this well-illustrated book meant for the general visitor to the Southampton meeting of the British Association for the Advancement of Science, or will it apply itself mainly to those whose minds can take in such detailed information and, so to speak, tell the tune from a glance at the musical score?

The present survey is a far cry from the 1882 *Guide to Southampton and Neighbourhood* ". . . prepared by Mr. Thomas W. Shore, of the Hartley Institution in that town [now city], in view of the approaching visit of the 'British Association'. A few pages are devoted to notes on climate, vital statistics, geology, botany, zoology, etc." (*Nature*, 26, 352; 1882). Prof. F. J. Monkhouse, professor of geography in the University of Southampton, who has been responsible for the editing of the present *Survey*, has guided his team of fifty writers well, and they have together prepared a comprehensive account of the region. In planning it they have divided the *Survey* into three parts. First, "The Character of the Region" (151 pp.), which deals with the geology, geomorphology, hydrography, soils, weather, hydrology and water supply, botany, zoology, land-use and the Hampshire Development Plan. Secondly, there is "The Historical Background" (68 pp.), and, finally, "The Character of the Town of Southampton" (111 pp.).

With a *Survey* of this nature, where each chapter deals with a specific aspect of a region and is packed with detail and facts, it is not possible in a limited space to review it as a whole. Instead, one can but take examples here and there to show just what can be found and what the area offers. In what follows here only Part 1 will be dealt with in detail, while Parts 2 and 3 will be treated briefly.

The introduction is a jointly written overture by Prof. F. J. Monkhouse and R. Douch. This deals with the region in very general terms and in an ideal racy style—sufficient to encourage the reader to probe on if not read on. One is promised excursions into the Hampshire mainland, Wiltshire, Dorset and the Isle of Wight, not only by land or sea, but also in time. The clock is set to start at the Cretaceous geological period and is wound to run until plans have been reached for the last quarter of the twentieth century.

The area which lies within the confines of the Hampshire Basin is of special interest to geologists, whether professional or amateur, especially for its wide range of Mesozoic and Tertiary formations accessible for detailed study along extensive coast line. These offer text-book exposures which, due to extensive coastal erosion, vary from year to year. Sections of beds ranging from the Lower Cretaceous Wealden Marls up to the highest British Oligocene strata are revealed for investigations with varying degrees of completeness; notable features are the Isle of Wight monocline, and the Winchester, Portsdown and Purbeck anticlines. Within the Cretaceous system are represented the Wealden Series, the Lower Greensand (Aptian and Albian), the Gault, the Upper Greensands and the Chalk. These are succeeded unconformably by rocks of the Eocene system including the Reading Beds, London Clay, Bagshot Beds, Bracklesham Beds, Barton Series and Lower Headon Beds. The Oligocene system present in the area incorporates the higher Headon Beds, Osborne Beds, Bembridge Series and Hampstead Beds. Superimposed on all these the geomorphologist will find particular interest in the chalklands, where smoothly curving slopes lead down to winding, dry valleys. Occasionally the land is divided into separate blocks by deep trenches through which the Rivers Stour, Avon, Test and Itchen flow. But, for the most, gentleness of slope is the order. In stark contrast the Tertiary rocks around Southampton itself give rise to dull featureless lowlands. However, the magnificent coastline elsewhere in the region owes much to the structures produced by the Alpine folding, and notable features are to be seen around the shores of the Isle of Wight, Portland Bill, Lulworth Cove, etc. In fact, the very forces of Nature responsible for these features are responsible for the wealth of the area—Southampton Water. Their results have had profound effect on the unusually providential tidal phenomena in the Solent which have made Southampton a unique port.

The creation of the English Channel had two main hydrological consequences. First, the progressive introduction of the semi-diurnal tidal pulse of the North Atlantic Ocean right into the Straits of Dover. Secondly, the opening of this converging gulf to the wave-action of the ocean with an immense fetch, along which the prevailing westerly gales can raise wave amplitudes of 30–40 ft. with pressures of up to 5 tons/ft.^{2}. The chapter on "Hydrography of the Solent and Southampton Water" deals with these tidal phenomena most effectively, along with such topics as, 'double' or prolonged high tides, synchronous tides, the Solent tidal stream, etc. The fortuitous circumstances which led to the formation of Southampton Water have endowed it with many favourable qualities: to name but a few, the unique tidal region, where for 8·75 h the water-level is either rising or standing and the ebb lasts only 3·75 h; the protecting and sheltering barrier of the Isle of Wight; excellent anchorage for the largest ships in the world, etc. The chapter is completed by sections dealing with hydrographic surveys and modern developments in Southampton Water.

From the point of view of soils, the region can be divided into those of the Tertiary Basin and those of the Chalk rim. Most of the soils developed in the Hampshire Basin can be assigned to three major groups: the podzolic soils, the brown earths and the gleys. Typical podzol profiles are to be found in the New Forest and Dorset heathlands. Gleys vary from those associated with brown earth to ground-water gleys, and, in the wettest gleys, peaty *A* horizons are to be found—these occur in most New Forest bogs. The Chalk outcrops over about 60 per cent of the region and provides a homogeneous parent material over considerable areas. Varieties of soil from these areas are the shallow rendzina deposits, the brown calcareous soils, clays and clays-with-flints—the last-mentioned originated under peri-glacial conditions and cap some of the Chalk ridges.

The coastal districts of central south England are noted for their warm, sunny summers and generally mild winters. These characteristics add together to make the region one of the most popular parts of Britain for summer holidays, and also for retirement. The chapter on weather and climate, after the short introduction, deals first with synoptic climatology in January and July. A section follows which treats the climatic elements throughout the year, including precipitation, snow, thunderstorms, temperature, ground frost, winds and fog. It is well illustrated with a map concerning annual precipitation 1916–50, and graphs of daily temperatures at Southampton in winter, monthly precipitation, droughts at Ventnor, Isle of Wight, temperatures at Southampton 1921–50, and diurnal variation of fog throughout the year at Calshot. Seven tables detail daily precipitation, temperature, average rainfall, snow or sleet, and ground fog.

In view of the ever-increasing demands of its expanding population and growing industries, Hampshire is fortunately 'stocked' from the point of view of water resources. While the average rainfall is only about 30 in., the Chalk forms a favourable factor with its porosity, fissures, well-defined bedding planes, etc. The minor folding has a general southward dip, and this is the broad direction of the surface drainage. The overlying Tertiary deposits in the south of the county are relatively impermeable. The chapter on hydrology and water-supply details flow measurement and ground-water observations, and the water supply of Southampton and the neighbouring district. It ends on an interesting historical note in the form of an appendix, "Hydrology in the Past", which discusses Saxon charter evidence, the anomalous Alre and water mills.

Several large tracts of natural and semi-natural vegetation have survived the encroachments of man in the region around Southampton. Among these, the New Forest, with its woodlands, heaths and bogs on Tertiary and Quaternary deposits, is outstanding. Inland, valleys of large rivers flowing off the Chalk provide examples of freshwater vegetation, marsh and water meadow. Much of the woodlands of the region consist of oak and beech, occasionally pine, birch, ash or alder carr. However, not only has much of the woodland been reduced in recent years, but also much of the grassland. Reduction in the rabbit population on Chalk downlands has led to reductions in the low-growing herbs due to vigorous growth of grasses, but seedlings of hawthorn and juniper are becoming established. In the New Forest excellent examples of heath and bog vegetation exist, while a notable series of valley bogs occur in the Matley and Denny Forest Nature Reserve incorporating bog-moss, cotton grass, bog myrtle and alder carrs. The large rivers flowing southwards from the Chalk into Southampton Water support, on the more waterlogged marshes of their alluvial flats, sweet-grass, reed, large sedges, etc. Without doubt the most important coastal species is *Spartina townsendii*. This vigorous maritime grass—only introduced into the area about a century ago—forms virtually monospecific swards over great stretches of mud bordering the coastline almost continuously from Hurst Castle to Chichester. More traditional salt marshes are represented only locally around the coast, ranging from *Aster tripolium* swards to mixed saltmarsh vegetation. The chapter on the botany of the region ends with a section in which the flora is described in detail under headings of: vascular plants; mosses and liverworts; fungi; marine algae; freshwater algae. Certainly the botanist, whether amateur or professional, cannot fail to find something of interest in the region.

As would be expected from such a diversity of habitat, the region has a rich and varied fauna. Worthy of special attention is the marine fauna of Southampton Water with extensive beds of *Mytilus* and the interesting American hard clam, *Venus mercenaria*. Wood-boring marine invertebrates are plentiful, especially *Limnoria* and *Teredo*. Demersal fishes include gobies, blennies, and, from time to time, sprats and herring. *Acartia* is dominant among the copepod species, while in deeper waters carnivorous mysids are to be found. The Chalk-streams provide a good habitat for trout, and of special interest to the freshwater biologist is the River Avon, which has been the focus of many special investigations by the University of Southampton from the point of view of salmon. Throughout the region invertebrates are plentiful, and recently three groups of nematocerous Diptera have aroused special interest: Chironomidae, Simuliidae and Tipulidae. Special mention should be made of the medicinal leech, *Hirudo medicinalis*, which, rare in Britain, is to be found in some New Forest ponds. Branchiopod crustaceans of interest are the rare *Triops cancriformis*, and the fairy shrimp, *Chirocephalus diaphanus*. In an average year it is claimed that Hampshire sees the recording of some 230 species of birds and, to mention but a few, these have included honey buzzards, kestrels, wood-larks, stone curlews, godwits, egrets, white stork, nightjar, wintering white-fronted geese, various buntings and goshawks. The British mammal fauna is well represented in the region and includes fallow, red, roe, sika and a few escaped chinese water deer, fox, badger, otter, red and grey squirrel (the former ousted from the mainland region by the latter, but still to be found on the Isle of Wight), rabbit, vole, hare, etc. Of special interest are the representatives of Chiroptera, as the region is one of the richest areas in the British Isles for bats. Of marine mammals, porpoises and dolphins have been found. All six British species of reptiles are present.

The chapter on "Land Use, Agriculture, Forestry and Conservation" opens on a historical note. Later sections deal with modern agricultural trends, the present agricultural pattern, land classification, land use and sylviculture in the New Forest, and conservation. Of special importance is the last mentioned as much attention has been directed to improving the deteriorating conditions of the New Forest, the Chalk grasslands, and the tidal and fresh-water marshes along the coast. The chapter is well illustrated, with five graphs dealing with holdings, crop and livestock returns, crop acreages, and consumption of plant nutrients. Two maps show land classification in Hampshire and the New Forest.

"The Character of the Region" is rounded off with a descriptive chapter on the Hampshire Development Plan. The background to the Plan is described and sections are included on population and housing, industry and employment, road developments, social facilities, areas of comprehensive development, and areas of special interest.

Part 2, "The Historical Background", opens with a chapter in which an endeavour is made to define the mysterious region of Wessex. Theories are put forward as to how far the boundaries of Wessex spread, and the part played by Hampshire and Southampton. Wessex for many centuries lost its regional significance, but owes much of its revived popularity to Thomas Hardy. "Place Names of Hampshire" is a delight for all to read. The central position of Hampshire on the south coast of England has had a striking effect on its place-name structure. To the west of the Hampshire Avon, Celtic place-names become increasingly more frequent, while to the east of the county few pre-English names have survived. Sections deal with the earliest names, earthworks, Germanic names, Scandinavian names, Norman and French names, the New Forest and its place names in Domesday Book. The third chapter considers "Settlement in Prehistoric and Roman Times". This treats, in succession, the palæolithic, mesolithic and neolithic periods, the Copper and Bronze Ages, the Iron Age, and finally the Roman period. A thirty-two page section on the history of Southampton rounds off the historical background. This commences with pre-conquest Southampton, medieval Southampton and aspects of its industry and power, the civic authority, trade and communications, Southampton in the sixteenth and seventeenth centuries with the collapse of commerce and later the revival of the Town's trade, and the effect of war with Spain. This chapter ends with an account of Southampton in the eighteenth and nineteenth centuries.

It was fortunate that the editor of the *Survey* was able to include in his preface the fact that "Her Majesty the Queen, on the recommendation of the Home Secretary, was graciously pleased to raise by letters patent the Town and County of Southampton to the title and dignity of a City on 11 February 1964". Unfortunately, the text of the volume was in the press at that time, and hence it was not possible to change the title of the third part, "The Character of the Town of Southampton". Essentially, the chapters within this part of the *Survey* deal with the social pattern, economic activity, the port of Southampton, communications, aspects of the civic scene, the Ordinance Survey, the University and the planning of Southampton. Under "Social Patterns" sections are included on the past and present activities of the city, the growth of the residential area, population growth, social ecology, industrial development, employment, etc. The chapter on the Port of Southampton describes the functions and activities of the Harbour Board, comparative port traffic, the docks, and the effects on Southampton if the recommendations of the Rochdale Committee's report, *The Major Ports of Great Britain*, are implemented.

It is inevitable that as each chapter has been written by separate authors there should be a certain amount of overlap. Prof. Monkhouse is to be congratulated on keeping this to a minimum and for encouraging bibliographies with almost all chapters. The absence of a general index is to be deprecated; no doubt its absence was necessary for the sake of expediency of publication. However, it is greatly to be hoped that one will be issued as a supplement in due course.

PRESIDENT FOR 1965 OF THE BRITISH ASSOCIATION

SIR CYRIL HINSHELWOOD, O.M., F.R.S.

SIR CYRIL HINSHELWOOD, former Dr. Lee's professor of chemistry in the University of Oxford, has been elected president for 1965 of the British Association for the Advancement of Science. Sir Cyril will deliver his presidential address at the next annual meeting in Cambridge.

Sir Cyril is retiring from his professorship in Oxford and has been succeeded by Dr. R. E. Richards, F.R.S., Oxford University reader in physical chemistry (see p. 917 of this issue).

He was appointed to the chair in 1937, and he first organized the transfer of the Department from the historic cellars and converted bathrooms of Balliol and Trinity Colleges to the first laboratory for physical chemistry at Oxford, built with the support of a benefaction from Lord Nuffield. Here he strengthened and enlarged his school of chemical kinetics on a broad front, to include physical and biological systems; and during his tenure of office he was able to see the development by members of his staff of distinguished groups in numerous branches of physical and inorganic chemistry. Now he has left the Oxford Department, his plans for the further expansion of the physical chemistry laboratory are still continuing.

Sir Cyril's distinction has been recognized far and wide, by awards from many universities, from the Royal Society, and from scientific academies in many countries. He is a Nobel prize-winner and holder of the Order of Merit. He can claim the unique record of having been at the same time president of the Royal Society and of the Classical Association. The tercentenary celebrations of the Royal Society in which he played the leading part will long be remembered.

Not only has Sir Cyril been awarded the Copley Medal of the Royal Society (*Nature*, 196, 1025; 1962), but he was also the first recipient of the Leverhulme Tercentenary Medal (*Nature*, 192, 907; 1961) and was awarded the Medal for 1961 of the Society of Chemical Industry. This Medal, a senior award of the Society, is presented every two years for conspicuous services to applied chemistry by research, discovery, invention or improvements (*Nature*, 189, 22; 1961).

Sir Cyril is now retiring to his native London, but his future will not be a period of inactivity. By his election to a senior research fellowship at the Imperial College of Science and Technology he will be able to continue scientific work, and his counsel will also be valued by the many organizations with which he is associated.

174 *pp.* 71 *line and half-tone illustrations.* 21*s*

INTRODUCTION TO MODERN PHYSICS

274 *pp.* 82 *line and half-tone illustrations.* 25*s*

Edited by Dr. H. MESSEL, *Professor of Physics, and*
Dr. S. T. BUTLER, *Professor of Theoretical Physics in the University of Sydney*

Here in three very readable books is the background for appreciating the new achievements of physical science and its place in the world. They have been written by authorities in terms that the non-specialist can readily understand, and will also interest the wider audience that happily turns to televised science. They stress the unification of science; a theme that is being exploited by the Department of Physics of the University of Sydney under the spirited guidance of Professor Messel.

BRITAIN AND ATOMIC ENERGY: 1939-1945

MARGARET GOWING, *B.Sc. (Econ.), Historian and Archivist, United Kingdom Atomic Energy Authority*

This history of the United Kingdom Atomic Energy Project up to the time the first atomic bombs were dropped on Japan was commissioned by the U.K.A.E.A., and much use has been made of official documents in this the first authoritative account of Britain's part in the development of atomic energy. The book is in three parts: a study of feasibility; the independent work in North America and Britain; and the joint work in North America.

FAST NEUTRON PHYSICS

Edited by Gerald C. Phillips, Jerry B. Marion and Jacob R. Risser

This book contains the proceedings of the international Conference on Fast Neutron Physics. Chapters deal with neutron sources, spectra, and thresholds ; neutron induced reactions and inelastic scattering ; elastic scattering and resonances ; polarization ; and historical background.

464 *pages, illus., index* 63*s net*

THE EARTH SCIENCES

Problems and Progress in Current Research

Thomas W. Donnelly, Editor

Problems of the earth's interior and of structural geology are discussed by Sydney P. Clark, Jr., and Fred Donath. W. S. Fyfe deals with experimental petrology, Heinz Lowenstem with the mineralogy of skeletal material in sediments, and John A. O'Keefe with the earth's outer shell and with the composition of the moon. S. S. Wilks writes of the statistical approach to geological problems.

196 *pages* 45*s net*

NOBLE GAS COMPOUNDS

Herbert H. Hyman, Editor

This book is the proceedings of the first conference held on the subject and represents a complete summary of research in this field. The intense interest exhibited in the reaction of xenon stems from the important role that the inert gases have played in the development of theories of chemical combination.

404 *pages, illus., index* 90*s net*

A MODERN ALGEBRA FOR BIOLOGISTS

By Howard M. Nahikian

This is not a handbook of modern algebra but a textbook for advanced students which starts with the elements of set theory and the applications of sets to biological models, theory of probability, information theory, and linear graphs.

272 *pages, index* 72*s net*

MAN MUST EAT

By William Kershaw Slater

While many laymen and scientists are rightly concerned about the contamination to feed supplies through atomic fall-out, Sir William shows that survival itself is dependent upon the application of scientific knowledge, including nuclear physics, to food production.

128 *pages, index* 28*s net*

LONDON OFFICE: 6a, Bedford Sq., London, W C 1

NORTH-HOLLAND BOOKS

*ATOMIC COLLISION PROCESSES

Editor: M. R. C. McDOWELL, Mathematics Department, Royal Holloway College, University of London

> "The often-repeated argument that there are too many scientific conferences has little application here. In a rapidly expanding subject there seems to be no way of keeping in touch other than by meetings, which serve the purposes of stimulation, clearing the air, reporting and criticism as well as review and bibliography."
> J. B. Hasted—*Nature*

1964 6×9″ 1180 pp. *f* 126.00; £12 12s.

---

*PROGRESS IN LOW TEMPERATURE PHYSICS
Volume IV

Editor: C. J. GORTER, University of Leyden

The majority of the papers deal with metals and super-conductors, magnetic effects and nuclear orientation, and the properties of liquid helium.

1964 6×9″ 576 pp. *f* 63.00; 126s.

---

*DIFFERENTIAL EQUATIONS OF MATHEMATICAL PHYSICS

By N. S. KOSHLYAKOV, M. M. SMIRNOV and E. B. GLINER (Leningrad)

The constant demand from physicists, applied mathematicians and technologists for a complete exposition of the application of the fundamental mathematical disciplines led to the appearance of this book. A textbook by the celebrated Russian teacher of mathematics, the late Professor Koshlyakov.

1964 6×9″ 680 pp. *f* 60.00; 120s.

---

*DYNAMICS OF CHARGED PARTICLES

By B. P. LEHNERT

CONTENTS:

1. Introduction; 2. Basic equations; 3. Orbit theory; 4. Adiabatic invariants; 5. Macroscopic theory; 6. Magnetic compression; 7. Confinement of charged particles; 8. Stability; 9. Relativistic effects; 10. Radiation.

1964 6×9″ 278 pp. *f* 32.50; 65s.

---

*UNIFIED THEORY OF NUCLEAR MODELS

By G. E. BROWN, Nordita, Copenhagen

The language of many-body theory is employed to a large extent and should be readable for physicists who are not specialists in nuclear physics.

1964 6×9″ 180 pp. *f* 20.00; 40s.

POLLEN PHYSIOLOGY AND FERTILIZATION

Editor: H. F. LINSKENS, Botanical Laboratory, University of Nijmegen

SUBJECTS:

1. Physiology of the embryo-sac. 2. Biochemistry of pollen wall formation. 3. Metabolism of pollen tubes. 4. Boron and pollen tube growth. 5. Chemotropism of pollen tubes. 6. Controlled fertilization. 7. The incompatibility barrier.

1964 6×9″ 270 pp. *f* 40.00; 80s.; $11.20

CHEMISTRY: The Elements and Their Reactions

By Eric Hutchinson, Ph.D., Professor of Chemistry at Stanford University.

New (2nd) edition. 693 pages, illustrated. £3 3s. 6d.

INVERTEBRATE ZOOLOGY

By Robert D. Barnes, Ph.D., Associate Professor of Biology, Gettysburg College.

632 pages, illustrated. £3 10s. 0d.

INTRODUCTORY INSECT PHYSIOLOGY

By Robert L. Patton, Ph.D., Professor of Insect Physiology, Cornell University.

245 pages, illustrated. £1 18s. 6d.

CELL PHYSIOLOGY

By Arthur C. Giese, Ph.D., Professor of Biology, Stanford University. New (2nd) edition.

592 pages, illustrated. £4 0s. 6d.

ORGANIC CHEMICAL PREPARATIONS

By Frank D. Popp, Ph.D., Assistant Professor of Chemistry, Clarkson College of Technology, Potsdam, New York; and Harry P. Schultz, Ph.D., Professor of Chemistry, University of Miami.

392 pages, illustrated. £1 17s. 0d.

20th CENTURY CHEMISTRY

By Joseph I. Routh, Ph.D., Professor of Biochemistry, State University of Iowa. New (3rd) edition.

489 pages, illustrated. £2 16s. 0d.

FUNDAMENTALS OF CHEMISTRY

By L. Jean Bogert, Ph.D., Instructor in Experimental Medicine, Yale University. New (9th) edition.

636 pages, illustrated. £2 14s. 0d.

ATOMIC ENERGY ENCYCLOPEDIA IN THE LIFE SCIENCES

Edited by Charles Wesley Shilling, M.D., D.Sc., Consultant to the U.S. Atomic Energy Commission. Prepared under the auspices of the Division of Technical Information, USAEC.

474 pages, 268 illustrations, 98 tables. £3 13s. 6d.

COMPARATIVE ANIMAL PHYSIOLOGY

By C. Ladd Prosser, Professor of Physiology, University of Illinois; and Frank A. Brown, Professor of Biology, Northwestern University. (2nd) edition, 1961.

688 pages, illustrated. £5 8s. 6d.

Abnormalities of the Sex Chromosome Complement in Man

Designed as a handbook and as a source-book of data for analysis, this report contains records of 266 cases of abnormalities of the sex chromosome complement in man, from the Registry of Abnormal Human Karyotypes at the Medical Research Council's Clinical Effects of Radiation Research Unit in Edinburgh. There is also a brief review of research on the various sex chromosome abnormalities and an account of the general features of individuals with these abnormalities.

Vital International Research Journals

Biorheology
Editors-in-Chief: **A.L.Copley**, Department of Physiology and Pharmacology, New York Medical College,
G.W.Scott Blair, Department of Physics, National Institute for Research in Dairying, Reading, Berks
Biorheology comprises the study of deformation and flow of biological systems of materials directly derived from living organisms. Such problems have recently assumed an increasing importance in physiology, medicine, surgery, botany and other biological disciplines. This quarterly journal publishes work in English, French and German concerned with process in the living organism (*in vivo*) *and with materials originating from the organism* (*extra-corporeal*). *The inter-relationship is stressed between rheological properties of biological systems and their various structural aspects.*

Experimental Gerontology
Edited by: **A.Comfort**, Department of Zoology, University College of London
A new quarterly journal promoting experimental study of the mechanisms of senescence in organisms, containing accounts of age-dependent processes at the cellular or molecular level, and providing review articles surveying experimental work in the same field. There are theoretical and critical articles supported by, or giving immediate rise to, experimental investigations. Recently published books on the subject are reviewed.

Journal of Chronic Diseases
An International Journal Devoted to the Problems and Management of Chronic Illness in all Age Groups
Edited by: **L.Lasagna**, Baltimore, Maryland, and **D.Seegal**, New York
The Journal of Chronic Diseases, published monthly, contains significant articles dealing with various phases of chronic illness of all age groups. These include studies of the natural history of chronic disease, early diagnosis, treatment, the impact of the chronically ill on the community, long-term medical and nursing care, rehabilitation, and preventive medicine.

Carbon
An International Journal sponsored by the American Carbon Committee
Editor-in-Chief: **S.Mrozowski**, State University of New York at Buffalo
Carbon is a quarterly journal devoted to the physics and chemistry, as well as to the scientific aspects of the technology, of a class of materials ranging from organic crystals and polymers through chars and carbons to graphite.

Infrared Physics
Board of Editors: **G.A.Boutry**, Laboratoires d'Électronique et de Physique Appliquées, Paris;
P.Goerlich, Director for Research and Development, VEB Carl Zeiss, Jena, E. Germany;
T.Moss, Royal Aircraft Establishment, Radio Department, Camberley, Surrey;
S.Passman, The RAND Corporation, Santa Monica, California;
W.K.Weihe, U.S. Army Engineer Research and Development Laboratories, Fort Belvoir, Virginia
Established for the publication of scientific papers concerning infrared physics and its application, this quarterly journal is concerned with infrared theory, experiment, and instrumentation as applied to infrared detection and transmission and to problems of atmospheric, meteorological, geophysical, astrophysical and space research.

Medical Electronics and Biological Engineering
Official Organ of the International Federation for Medical Electronics
Edited by: **P.E.K.Donaldson**, Physiological Research Laboratory, Cambridge
This quarterly keeps key personnel and top research executives throughout the world right up-to-date in the fast expanding field of medical electronics by rapid interchange of research information and by bringing them news of new techniques and instruments.

International Journal of Nursing Studies
Edited by: **Elsie Stephenson**, Nursing Studies Unit, Edinburgh
A quarterly journal which publishes papers on all aspects of nursing and the allied professions throughout the world. Emphasis is placed on three main aspects – meeting the community's needs for all types of nursing care; preparing young people for assuming nursing duties and responsibilities; and encouraging all aspects of nursing research.
Contributions are invited for publication in these journals. For information on length and style of manuscripts, please write to the most convenient address given below.
A free specimen copy of any journal, together with details of subscription rates, will be sent on request.

Pergamon Press Publications

Significant Autumn-List Books

Collected Papers of P.L.Kapitza, Volume 1—1916–1934

Edited by **D.ter Haar**

Partial Contents:

Electron inertia in molecular Ampère currents; The preparation of Wollaston fibres; The Koch recording microphotometer; A method of producing strong magnetic fields; The Zeeman effect in strong magnetic fields; Over-tension in a condenser battery during a sudden discharge; Metallic conductivity and its change in a magnetic field; A property of superconducting metals; Magnetostriction of diamagnetic substances in strong magnetic fields; A method of measuring magnetic susceptibilities; The liquefaction of helium by an adiabatic method.

520 pages. £7 ($20.00)

Genetics Today

Proceedings of the XI International Congress of Genetics, The Hague

Edited by **S.J.Geerts**

Partial Contents of Volume 1 (Abstracts of Volumes 2 and 3)

Complex loci; Recombination; Molecular and microbial genetics; Gene action; Mutagenesis; Cytology; Population genetics; Human genetics; Dermatoglyphics.

352 pages. 100s. ($15.00)

Partial Contents of Volume 2:

Genetic fine structure in relation to the function in Neurospora – N.J.Giles; A theory of crossing-over and gene conversion involving Hybrid D.N.A. – H.L.K.Whitehouse; Regulation of gene action in maize – D.Schwartz.

Approx. 450 pages. 100s. ($15.00)

Partial Contents of Volume 3:

The nature and consequence of interference amongst plants – J.L.Harper; Syntheses – K.Mather; The genetics of incompatibility – A.Lundquist; Cytogenetics and plant breeding – R.Riley; Dermatoglyphs in mosaic mongolism and allied conditions – L.S.Penrose.

Approx. 450 pages. 100s. ($15.00)

Variation Methods in Mathematical Physics

S.G.Mikhlin

Contents:

On the operators of mathematical physics; Energy convergence; The energy method; Major applications of the energy method; Problem of Eigen-values; Generalization of preceding results; Estimates of error of an approximate solution; Numerical examples; The Bubnov–Galerkin method; The method of least squares; The methods of finite differences.

616 pages. 100s. ($14.50)

Handbook of Radiochemical Exercises

A.N.Nesmeyanov

Contents:

Preface; Introduction; Equipment of radiochemical laboratories and peculiarities of work involving radioactive substances; Nuclear radiation and methods for its measurement; Decay and growth of radioactive isotopes; Production and properties of radioactive isotopes; Application of radioactive isotopes as "Labelled Atoms"; Appendix.

458 pages. 84s. ($12.00)

Biochemistry of the Poliomyelitis Viruses

E.Kovács, University of Toronto

Partial Contents:

The biological, biochemical and epidemiological aspects of poliomyelitis of man and animals; Experimental poliomyelitis; Biochemical data of polio virus; Further considerations on the general biology, biochemistry and pathology of experimental poliomyelitis infection in animals; The host cells in general; Some cytological and biological effects of poliomyelitis virus infection on cultivated cells; The role of heredity; Facts and speculations on the biosynthesis of the polio virus; Chemical, physical and biological foundation of virus research; Biochemical aspects of some other features of the virus problem.

International Series of Monographs on Pure and Applied Biology, Modern Trends in Physiological Sciences Division, Volume 21.

280 pages. 70s. ($10.00)

Pharmacology of Smooth Muscle

Edited by **Edith Bülbring,**
Department of Pharmacology,
University of Oxford

Partial Contents:

Electrophysiological effects of adrenergic nerve stimulation – Mollie E.Holman; The inhibitory action of adrenaline. Biochemical and biophysical observations – E.Bueding and Edith Bülbring; Excitation, contraction and calcium in smooth muscle – H.J.Schatzmann; The mechanism of action of acetylcholine – W.D.M.Paton; Cholinergic junction potentials in intestinal smooth muscle – J.S.Gillespie; Hormonal control of myometrial contractions – Brenda M. Schofield; Effect of electrolytes on the membrane activity of the uterus – H. Kuriyama.

Proceedings of the Second International Pharmacological Meeting, Volume 6.

A leaflet containing full details of all volumes is available on request.

168 pages. 50s. ($7.50)

ZEISS

Electron Microscope EM9

The EM9 has been specially developed to meet the increasing demand for an instrument which will produce high quality micrographs rapidly and with the greatest simplicity.

Main features include:—

- Automatic film exposure control.
- Automatic numbering of film sequence.
- Automatic transport for 20 cut films.
- Fully automatic vacuum system.
- Specially designed binocular viewing tube 10x for spectacle and non-spectacle wearers.
- Built-in high voltage 60 kv 'Cascade' unit.
- Novel specimen stage.
- Short pump-down time.
- Fixed step magnifications 1,500x, 5,000x, 16,000x & 35,000.
- Variable magnification 0 to 35,000x,
- Electromagnetic 3-lens imaging system.
- Point resolution in routine work better than 20 A.
- Test micrographs obtained 12A point resolution and 10.5A line resolution.

Russian Translation Programme

PHYSICOCHEMICAL MECHANICS OF METALS

V. I. LIKHTMAN, E. D. SHCHUKIN
and P. A. REBINDER

The book deals first with the plasticising influence of weak surface-active substances, such as the various organic compounds, with specific application to problems of lubrication and machining, and then considers the effects of strong surface-active agents, i.e. of liquid-metal coatings on solid metals, with reference to problems of crack propagation, and failure of solids. The brittle-to-plastic transitions in metals under the influence of liquid coatings is extensively covered. For all concerned with the applied problems of metallurgy, and of strength of materials, this is an invaluable work.
244 pages. 9⅝″ x 6⅝″ **90s.**

FISHES OF THE NORTHERN SEAS OF THE USSR

A. P. ANDRIYASHEV

This is a manual for the classification and identification of all the marine and anadromous fishes of the northern seas of the USSR and of the adjacent waters, from the Barents Sea to Iceland. Annotative synonymies for Arctic fish are published here for the first time. 237 (221+16) species and subspecies belonging to 134 genera, 54 families, and 22 orders, are described.
618 pages. 9⅝″ x 6⅝″ **£6.15s.**

FAUNA OF THE USSR—Crustacea

Ya. A. BIRSHTEIN

Carcinologists will find this a welcome addition to the series on crustaceans. It is concerned with freshwater isopods (sub-order Asellota) belonging to the families Asellidae, Janiridae, and Microparasellidae. The introductory chapter contains a comprehensive survey of water skaters, their evolution, morphology, physiology, habits and economic uses. 56 species are described in detail. Keys and an index of Latin names are included.
148 pages. 9⅝″ x 6⅝″ **40s.**

Lock PORTABLE

CONDUCTIVITY

BRIDGE TYPE BC 1

This fully-transistorized instrument has a bridge frequency of 1500 cycles per second, and it covers directly the wide range of 0·5 to 1 × 10⁶ micro mhos in 7 ranges.

A similar bridge, but powered from the A.C. mains supply, is also available. This covers the very wide range of 0·05 to 1 × 10⁶ micro mhos in 8 ranges.

NGN OFFER YOU

PENNING CONTROL UNIT MODEL 1

(a) Range 10^{-2} to 10^{-6} torr in two ranges.
(b) For use with Penning gauge head Type PG.1.
(c) Facility for external meter or recorder.

THERMOCOUPLE CONTROL UNIT MODELS 1-2 and 1-6

(a) For use with Thermocouple gauge Type TC.1
(b) Range 10 to 10^{-3} torr in one range.
(c) Model 1-2 supplies 2 heads.
(d) Model 1-6 supplies 6 heads.
(e) Heads interchangeable without re-setting the control unit.
(f) Battery operated and completely portable.
(g) Mains operated units available on request.

THERMO-PEN CONTROL UNIT MODEL 1

(a) For use with Penning gauge Type PG.1 and two Thermocouple gauges Type TC.1.
(b) Covers the ranges 10 to 10^{-3} torr and 10^{-2} to 10^{-6} torr.
(c) Mains operated.
(d) Each circuit incorporates all the features of the above instruments.

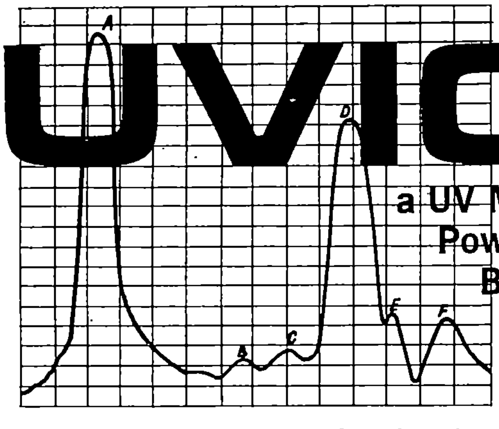
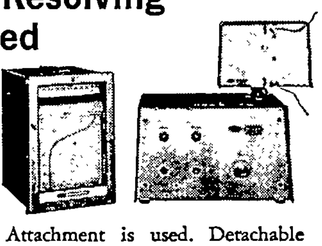
UVICORD



a UV Monitor with High Resolving Power and Unsurpassed Base Line Stability



For continuous-monitoring of the effluent from chromatographic and electrophoretic columns. The *Uvicord* measures UV absorption at 2537 Å and possesses such high volumetric resolving power and photometric stability that in many cases quantitative as well as qualitative measurements can be made. Applicable to proteins, certain peptides and amino acids, cyclic hydrocarbons, nucleosides and nucleotides, purines and pyrimidines, some steroids, and to all other substances having sufficient absorption at 2537 Å. The small dose of UV radiation administered to the sample in the measuring cell leaves even UV-sensitive substances virtually unaffected. Operation in a coldroom is possible when LKB 4740A Coldroom-Attachment is used. Detachable optical unit contains stable mercury lamp, adjustable slit, liquid ultraviolet filter, black glass filter, low-volume measuring cell of quartz with inlet and outlet connectors for Teflon capillary tubing, and vacuum phototube. Control unit contains light-intensity stabilizer and d.c. amplifier. Connections are provided for the LKB 6520 D.C. Recorder and for standard 10-mV or 100-mV potentiometer recorders. Provisions for fraction marking are included with the 6520A.

THE BEAUMARIS FRACTION COLLECTOR. MK. 2

Simple and reliable

One plate takes 3 sizes of tubes. 150 each 15, 7 and 3 ml., or 250 of any one size, or will now take up to 350 tubes of 12 cc. Time, Volume or drop counter controlled. Sockets provided for event marker on all current models. As used by London's leading teaching Hospitals and many Universities.

Collectors from £125 complete.
Fully transistorised Drop Counter and Time Switch £105

Models made for rimless tubes.
We will also make Collectors to your requirements.

BALL DRILLING JIG

We now make a precision Universal Ball Drilling Jig, for building Crystal Structures.
Price £30.

Please write for particulars. Everything we make sent on approval.

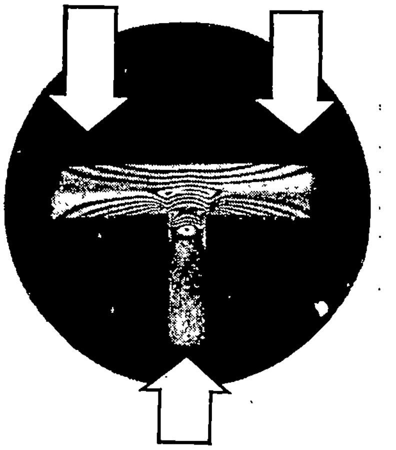
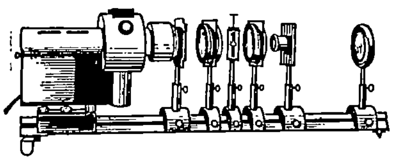
REVEALING THE EFFECTS OF
STRESS



IMPORTANT APPLICATIONS OF SPINDLER & HOYER OPTICAL BENCHES



Beam of light from carbon arc lamp is gathered in optical condensers, transmitted through polarizing screen, specimen, analysing screen and objective, which projects it on viewing screen. Spindler & Hoyer optical benches feature an automatic feeding device to move carbons uniformly through the lamp and eliminate adjustment. A wide range of sliding carriages and other accessories makes them extremely versatile.

(2) TEACHING

When specimens of plastic or special glass are fitted to a Spindler & Hoyer optical bench and subjected to stress, an image showing the effects is projected for observation. It may be filmed or photographed as a record. The instrument provides lecturers with a particularly graphic means of illustrating the principles of mechanics at work.

Industrial applications are numerous—Spindler & Hoyer optical benches are valued as time and money-saving equipment in many leading laboratories. For example, they are used to test glass and plastic mixes and product designs before manufacture, and to investigate the effects of stress on engineering projects at the technical design stage. For full details, please contact the sole U.K. distributors,

LETTERS TO THE EDITOR

SPACE SCIENCE

Variations in Upper-atmosphere Density between Sunspot Maximum and Minimum

The atmospheric density at heights of 200–800 km has now been quite thoroughly charted during a complete half-cycle of solar activity from the intense sunspot maximum in 1957–58 to the solar minimum in 1964. Nearly all the information has come from investigations of the changes in satellite orbits caused by air drag, from which the air density at heights a little above perigee height can be deduced[1]. These investigations have shown that at heights of 200–800 km the atmospheric density and temperature are strongly under solar influence: they depend on the presence or absence of solar radiation (the day-to-night effect), and also respond vigorously to changes in solar activity.

Day-to-night effect. At any given height between 250 and 800 km, the air density increases during the morning and reaches a fairly sharp maximum at about 14 h local time. It then declines until midnight, reaches a flat minimum between midnight and dawn, and begins its morning increase again[2–7]. Although the day-to-night changes are most conveniently described in this way, in terms of local time, the description is slightly misleading, since the density and temperature depend primarily on the elevation of the Sun above the horizon, showing a roughly circular symmetry about a point on the Earth which is vertically beneath a 'mock Sun' that lags some 2 h (30°) behind the real Sun[8]. Thus the Sun, as it were, draws up the atmosphere into a bulge centred at a point on the Earth almost underneath the Sun. At any given latitude and height, the density does show the daily variation described, with a maximum at 14 h; but the maximum density is only reached in near-equatorial regions, and in the darkness of the polar midwinter the density will exhibit a night-time value, even though the local time may be noon.

The day-to-night variation is small at a height of 200 km, but at greater heights becomes extremely large. Fig. 1 shows the variation with height of both the maximum day-time density (full lines) and minimum night-time density (dot-dash lines) in various years from 1958 until 1964, as determined[9] from the orbits of the 45 satellites found to be suitable for the purpose. The day-time values for 1963 and 1964 were not distinguishable and are given as one curve in Fig. 1; similarly for the 1962–64 night-time values. Some curves have also been truncated to improve clarity. If the ratio (maximum day-time density) ÷ (minimum night-time density) is denoted by f, then, for 1959 when solar activity was high, the value of f increased from about 1·1 at a height of 200 km, to 1·6 at 400 km and 5·5 at 600 km[10,11]. As solar activity declined, the-day-to-night effect began to extend down to lower altitudes: thus in 1964, f exceeds 2 at a height of 250 km, increases to 2·8 at 400 km, and then to a maximum of 4 at 500 km, before decreasing slowly at greater heights[3,9,12].

Response to solar activity. Although the day-to-night variation in air density is large, the variations due to solar activity can be even larger. As Fig. 1 shows, the upper-atmosphere density has greatly decreased as solar activity declined from its intense maximum in 1957–58 to its minimum in 1964. At a height of 200 km the maximum day-time density was 1·6 times lower in 1964 than in 1958; at 400 km, 6·7 times lower; and at 600 km, 32 times lower.

Quite apart from these large changes over the long time-scale of the solar cycle, the temperature and density also respond to the shorter-term variations in solar activity, exhibiting the 27-day recurrence tendency which is characteristic of solar activity, and showing a striking correlation from day to day with various indices of solar activity, such as the planetary geomagnetic index and the solar radiation on 10·7-cm wave-length[2,4,8,13–16]. During the greatest magnetic storms, the density increases for a few hours by a factor of 6 at heights near 600 km and the temperature increases by about 500° K; but even minor changes in solar activity are faithfully reflected in the density and temperature of the upper atmosphere[14,15].

Mechanism of solar control. It appears that at heights above about 300 km the atmosphere may, despite its wide variations, be regarded as in a state of diffusive equilibrium, with temperature almost independent of height[17]. The temperature above 300 km is, however, strongly dependent on the level of solar activity and the time of day: the maximum day-time temperature varies between 2,000° K in a year of very high solar activity (for example, 1958) and 900° K at solar minimum. The minimum night-time temperatures are 25 per cent lower[8,15].

The solar influence over upper-atmosphere temperature is exercised primarily through the heating effect of extreme ultra-violet radiation from the Sun (wave-lengths probably about 200–1000 Å), which is absorbed mainly at heights between 100 and 200 km[15,18]. The quiet solar wind, the stream of charged particles continually flowing out from the Sun at speeds of order 500 km/sec, also probably causes heating as a result of its interaction with the outer boundary of the Earth's magnetosphere; and this heating effect due to charged particles is greatly enhanced when the Sun is very active and the particles ejected from it are more numerous and energetic.

Other variations in upper-atmosphere density. Although the main variations in upper-atmosphere density and temperature are the day-to-night effect and the fluctuations dependent on solar activity, there is a smaller but

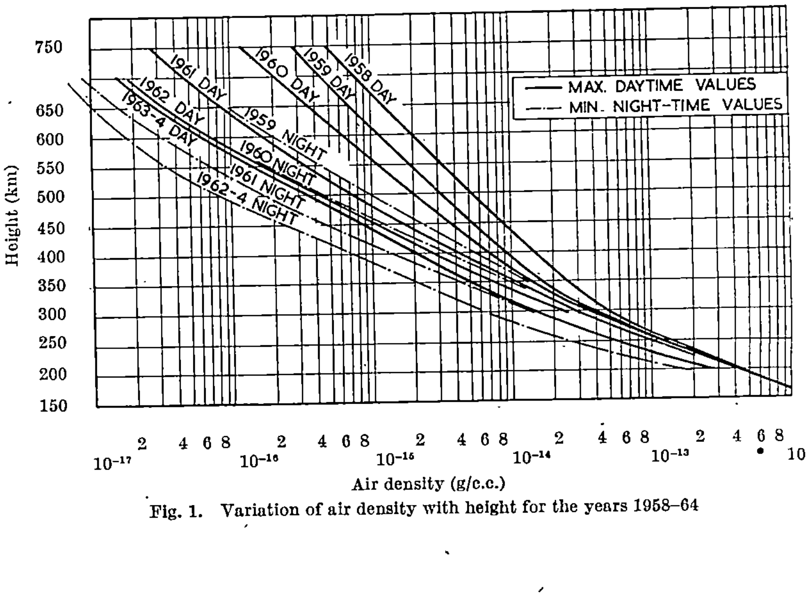

Fig. 1. Variation of air density with height for the years 1958–64

still appreciable effect associated with the time of year. Upper-atmosphere density and temperature undergo a semi-annual variation with minima in January and July, and maxima in April and October. Generally, however, the July minimum is lower than that in January, and the October maximum is higher than that in April[19,20]. These variations amount to about ± 100° K in temperature, and ± 20 per cent in the density at a height of 350 km[8,20]. The effects are probably linked with the variation in the Earth's distance from the Sun during the course of a year, and variations in the interaction of the solar wind with the Earth's outermost atmosphere.

At heights outside the range 200–800 km the results obtained from satellite orbits are less satisfactory. For heights of 150–200 km, the lifetimes of the satellites are uncomfortably short and the drag coefficients are somewhat uncertain. However, it is established that the day-to-night effect reverses at heights of 150–200 km, the density being slightly greater by night than by day[21–24], and it seems that the density is much less dependent on solar activity than it is at greater heights. At heights above 800 km, data from satellites are as yet rather sparse, since only balloon-satellites exhibit orbital changes large enough to be accurately measured. The main variations at heights up to 2,000 km, however, still appear to be due to solar activity and the day-to-night effect[5,16,25,26].

ASTRONOMY

Lunar Brightness Distribution at 1·5 mm Wave-length

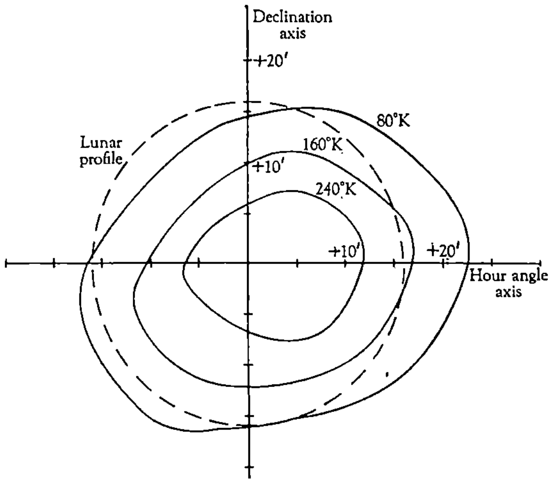

Fig. 1. Lunar micro-wave isotherms at 1·5 mm. Phase 136° after new moon. Detector, Golay cell. Entrance aperture of collecting cone 15 mm, giving angular response function of approximately gaussian form, with standard deviation 8·4 min of arc

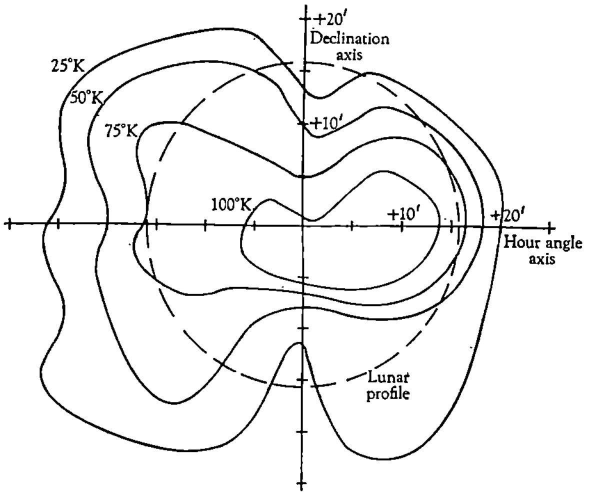

Fig. 2. Lunar micro-wave isotherms at 1·5 mm. Phase, 45° after new moon. Detector, indium antimonide photo-conductor at 11·7° K. Entrance aperture of 8 mm giving angular response function of approximately gaussian form with standard deviation 5·0 min of arc

WE have recently measured the microwave brightness temperature over the lunar disk using a new 1·5 m aperture Cassegrain telescope with both cooled indium antimonide and Golay cell detectors. The measurements cover a fairly broad band centred at 1·5 mm and with a mean wave-length deviation of about 0·2 mm[1]. The results of solar scans show that the angular response function of the telescope when used with either detector is of approximately Gaussian form. The results of two series of lunar drift curve measurements are shown in isothermal form in Figs. 1 and 2. The results have been corrected for the time constant of the detector circuit but not for the angular response function of the telescope.

The measurements show a much greater poleward darkening than that found from infra-red measurements[2], and in this respect our results agree with previous microwave measurements at higher wave-lengths[3,4].

Measured microwave temperatures are a function of the electrical and thermal properties of lunar material (since the surface is partially transparent to radiation at these wave-lengths). In the case of a plane homogeneous or stratified model, however, theory[5] predicts that the mean microwave temperature $\overline{T}_\lambda$ over a whole lunar cycle is related to the mean surface temperature $\overline{T}_0$ by the relation:

$$\overline{T}_\lambda = (1 - R_\xi)\overline{T}_0 \qquad (1)$$

where ξ is the zenith angle of the point of observation at the lunar element being considered and R_ξ is the reflexion coefficient corresponding to this angle. For two small regions, one located on the lunar equator and the other on the lunar meridian passing through the centre of the lunar disk both having the same angle ξ, equation (1) shows that:

$$\frac{\overline{T}_{\lambda 0}}{\overline{T}_{\lambda\psi}} = \frac{\overline{T}_{00}}{\overline{T}_{0\psi}} \qquad (2)$$

In this equation the second suffix refers to the lunar latitude ψ in each case, so that $\overline{T}_{\lambda\psi}$ and $\overline{T}_{\lambda 0}$ are the microwave temperatures of the two regions and $\overline{T}_{0\psi}$ and $\overline{T}_{00}$ are the corresponding surface temperatures which can be calculated from the infra-red measurements[2]. Each of the microwave measurements shows a systematic disagreement with equation (2) and in each case the ratio $\overline{T}_{\lambda 0}/\overline{T}_{\lambda\psi}$ is significantly greater than the value of $\overline{T}_{00}/\overline{T}_{0\psi}$ determined from infra-red measurements.

We think that this disagreement between the microwave results and the theory of plane stratified model is due to surface roughness. Near either lunar pole only a small fraction of the facets of a rough surface will receive solar radiation and because of the T^4 radiation law the mean temperature of the lunar material (from which the microwave radiation comes) will be lower than that from a macroscopically smooth surface. The same considerations do not apply to nearly the same extent for a point on the lunar equator since a much larger fraction of facets is illuminated during a lunation. The size of the roughness elements is somewhat less than that suggested recently from the results of other measurements[6], thus implying a size distribution of linear dimensions of the roughness elements. The properties of the lunar surface thus indicated are not dissimilar from those of the hierarchical-void model proposed by Troitskii[7], but they do not seem to be consistent with those theories which suggest a uniform flat layer of fine dust.

We thank Dr. E. H. Putley and his colleagues of the Royal Radar Establishment, Malvern, and Dr. D. H. Martin of this Department for their help in the installation and operation of the cooled indium antimonide detector.

Note added in proof. It is hoped that the recent American close-range lunar photographs, obtained since the communication of this letter, can be used, by extrapolation, to give an estimate of the density of microcraters of size below 1 cm, which might give rise to the roughness described here.

Rotation of the Globular Cluster ω Centauri

A long series of observations and measurements of photographic plates taken on the globular cluster ω Centauri has now been completed by members of the staff of the Royal Greenwich Observatory at Herstmonceux. The observational material was obtained at the Radcliffe Observatory in Pretoria and at the Royal Observatory at the Cape of Good Hope, with the co-operation of the Radcliffe Observer, Dr. A. D. Thackeray, and of H.M. Astronomer at the Cape, Dr. R. H. Stoy, respectively. Details will be published in the *R.G.O. Annals* and *Bulletins* shortly, but special attention is directed here to the fact that the cluster has been observed to be rotating, and that the rate of rotation agrees with a theoretical value deduced from the ellipticity of the cluster. The view is therefore supported that the structure of the cluster is given by an appropriate modification of the isothermal gas sphere, and, moreover, that the elliptical shape of the cluster is a consequence of a rotation considerably greater than galactic rotation. This latter result disposes of the view that the elliptical shape is a consequence of galactic tidal forces.

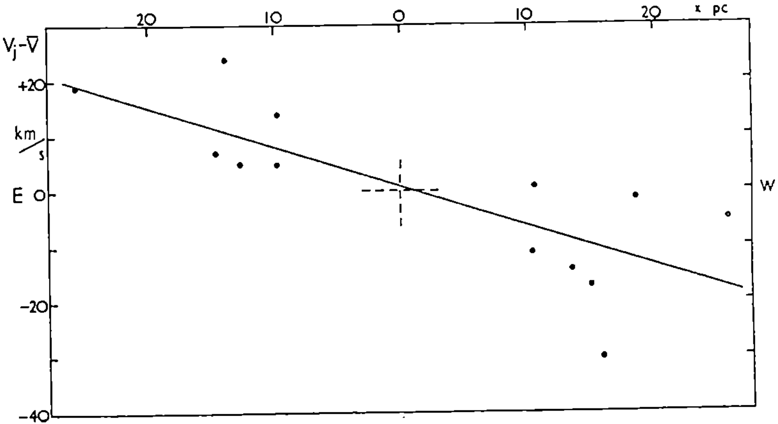

Fig. 1. Radial velocity plot. Excess radial velocity against distance from axis of rotation

As the brightest stars of the cluster are of the thirteenth magnitude, it is no easy matter to determine their radial velocities individually, but the work was done by Mr. G. A. Harding, using fast cameras on the Cassegrain spectrograph of the 74-in. telescope at the Radcliffe Observatory. As the result of two seasons' observing, he secured three spectra of each of thirteen stars known to be cluster members from other studies at Herstmonceux. The results were analysed to determine the velocity dispersion due to instrumental error, the true dispersion of the velocities of the star, and also the projection of the rate of rotation of the cluster normal to the line of sight. The latter two quantities were found to be:

$$\sigma = 10 \pm 4 \text{ km/sec}$$

$$\text{and} \quad V - \bar{V} = (0{\cdot}72 \pm 0{\cdot}18)x + (0{\cdot}9 \pm 2{\cdot}8) \text{ km/sec} \qquad (1)$$

where x is the distance from the axis of rotation in parsecs. The observations on which this result is based are illustrated in Fig. 1.

All the stars brighter than the 16th visual magnitude have been catalogued (except for the centre of the cluster where the count terminated at the 14th magnitude on account of the crowding of images) and the counts were corrected for the presence of non-cluster members on the plate by an appeal to an extensive series of proper motion measurements. From an analysis of the count it was found that the lines of equal star density are roughly circular at the centre and in the extreme outer parts, but that the eccentricity rises to a maximum at about 8 parsecs from the centre of the cluster where the ratio of the axes is 0·81 as seen in projection. This corresponds to 0·86 if the axis of the cluster is normal to the line of sight. The ratio of the axes is plotted against distance from the centre in Fig. 2. The detailed reductions have been carried out for the most part by Mr. R. J. Dickens.

If the cluster behaves like a (truncated) isothermal gas sphere, it is characterized by a scale-length l and a characteristic velocity j^{-1}. These are observed to be $l = 1$ parsec and $j^{-1} = 8$ km/sec from the observed velocity dispersion. With these constants established we can make use of a theoretical argument by Woolley and Dickens[1] to determine the rate of rotation of the cluster from the observed eccentricity. The result of this calculation is $\omega = 0{\cdot}55 \pm 0{\cdot}25$ km/sec/parsec, in very reasonable

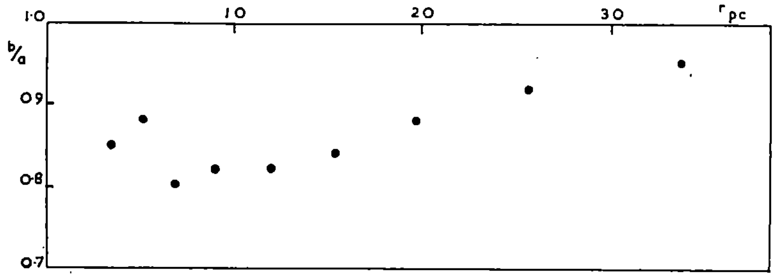

Fig. 2. Ratio of axes as a function of radius

agreement with the observed value of 0·72 ± 0·18 km/sec/parsec. In both cases it is assumed that the axis of rotation is normal to the line of sight. In comparison, the rate of rotation of the galaxy is only about 0·025 km/sec/parsec.

Since the outer parts of the cluster are more or less spherical, it must be supposed that they have not yet been brought into equilibrium with the inner parts by interstellar collisions, and indeed one might attempt to estimate the age of the cluster by calculating the time of relaxation at that point where the eccentricity begins to fall away. Only approximate figures can be given, but the time of relaxation 8 parsecs from the centre is about 4×10^9 years.

RADIOPHYSICS

Observations of Solar X-ray Emission in the Band 44–60 Å from U.S. Naval Research Laboratory Satellite *1963-21-C*

The U.S. Naval Research Laboratory has instrumented a series of satellites for the investigation of solar X-ray and ultra-violet emissions[1,2]. It has generously allowed the Radio Research Station, Slough, to participate in these experiments and has provided the necessary information for reducing telemetry data. This communication presents some results for X-rays in the band 44–60 Å derived from telemetry recorded from satellite *1963-21-C* at the D.S.I.R. Radio Research Minitrack Station at Winkfield during June–July 1963. The principle of the experiment has been used on previous satellites and has been described by Acton *et al.*[3].

The satellite was launched into an elliptical orbit with perigee of approximately 190 km, but, in spite of the relatively low satellite heights, measurements made at small solar zenith angles showed little evidence of atmospheric absorption. In Fig. 1 are shown the X-ray fluxes measured at ½-min intervals during a satellite pass on July 23, 1963. These X-ray fluxes have been derived assuming a spectrum corresponding to a source temperature of $0{\cdot}5 \times 10^6$ °K (ref. 3). The accuracy of these measurements is estimated to be better than 5 per cent[4]. Although the satellite height changed by almost 20 km over the pass, no significant change in flux was noticed.

In order to estimate the possible attenuation of the fluxes by atmospheric absorption, calculations of the optical depth, τ, at each position of the satellite have been made using the relation:

$$\tau = \sum_s (n_s H_s \sigma_s) \sec \chi \qquad (1)$$

where n_s and H_s represent the number density and scale height of the absorbing gas at the satellite and σ_s the absorption cross-section; the summation includes the effects of O_2, N_2 and O constituents in the atmosphere. In this calculation use has been made of the atmospheric model appropriate to local noon at sunspot minimum conditions, as proposed by Harris and Priester[5], and the following values of mean absorption cross-sections have been adopted:

$$\sigma_{O_2} = 4 \times 10^{-19}\ \text{cm}^2$$
$$\sigma_{N_2} = 2 \times 10^{-19}\ \text{cm}^2$$
$$\sigma_{O} = 4 \times 10^{-20}\ \text{cm}^2$$

These values have been taken from a summary of theoretical and experimental results given by Van Zandt[6] with account being taken of the variation in response of the detector over the wave-length range 44–60 Å.

This calculation has shown that the attenuation of X-ray fluxes presented in Fig. 1 is expected to be less than 0·3 per cent. These and other observations near noon have indicated that the solar flux remains fairly constant during the 5 to 7 minutes of the satellite pass.

Measurements near sunrise and sunset have shown marked changes in flux during a single pass. Fig. 2 summarizes the measurements made at intervals of 0·5 min during a pass beginning at 0252 G.M.T. on June 25, 1963; the first observation shown at 0253·20 G.M.T. was above the limit of the X-ray detector. Also shown is the variation during the satellite pass of the grazing height of solar rays, that is, the height of nearest approach to the Earth's surface; a reduction in this height implies an increase of atmospheric thickness traversed by X-rays received at the satellite. In order to examine whether the variation of X-ray flux during the pass can be explained quantitatively by atmospheric absorption, estimates of the optical depth at the satellite have been made using the Nicolet approximation[7]:

$$\tau = \sum_s n_s' \sigma_s \sqrt{\frac{\pi(R + h')}{2H_s'}} \left[1 + \operatorname{erf}\left\{ \tan\left(\chi - \frac{\pi}{2}\right) \sqrt{\frac{R + h'}{2H_s'}} \right\}\right] \qquad (2)$$

where R represents the radius of the Earth, h' the grazing height, and n_s' and H_s' the number density and scale

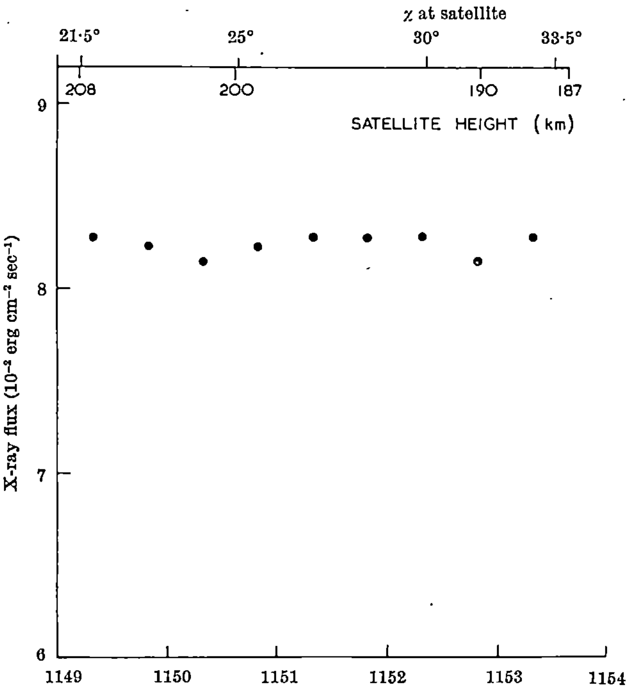

Fig. 1. Measurements of solar X-ray flux in the band 44–60 Å during a pass near noon on July 23, 1963

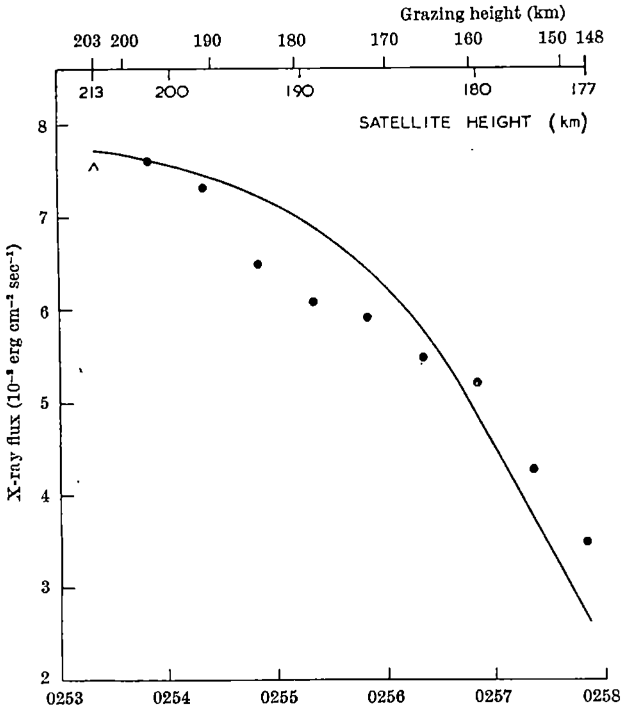

Fig. 2. Measurements of solar X-ray flux in the band 44–60 Å during a pass near sunrise on June 25, 1963, compared with the variation computed for a theoretical model of atmospheric absorption

height of the absorbing gas at the grazing height. Again the summation includes the effects of O_2, N_2 and O constituents. In these calculations the atmospheric model of Harris and Priester[5] applicable to early-morning hours at sunspot minimum has been adopted. The smooth curve of Fig. 2, which is normalized to the measurement at 0253·50 G.M.T., represents the variation of X-ray flux expected during the pass because of atmospheric absorption, assuming that the flux incident at the top of the atmosphere remains constant as observations near noon have indicated. It is evident that the slope of the theoretical curve depends on the accuracy of τ, given by expression (2), and hence on the values of absorption cross-section adopted and on the atmospheric model used. However, it seems reasonable to conclude that the variations of flux observed during passes near sunrise and sunset are almost entirely due to atmospheric absorption.

In conclusion, the observations indicate that the flux of solar X-rays in the band 44–60 Å during the period of low solar activity of June–July 1963 was near 8×10^{-2} erg cm^{-2} sec^{-1}. This value lies within the range of values found from rocket observations at sunspot minimum and sunspot maximum conditions[3]. In general, measurements made near 190 km show little evidence of atmospheric absorption except near sunrise and sunset.

The work described here was carried out as part of the programme of the Radio Research Board, and this communication is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

GEOPHYSICS

Fluctuations in Ionospheric Absorption Events at Conjugate Stations

BROWN[1] has recently presented observations of those ionospheric absorption events observed at Kiruna which fluctuate over periods of several minutes, and from it has concluded that the fluctuations are consistent with modulation of the electron precipitation by hydromagnetic waves. However, no detailed mechanism for this interaction has yet been proposed. The purpose of this communication is to present a complementary feature which any theory must take into account: namely, the phase relation between these fluctuations in magnetically conjugate regions.

A sample of the records from the conjugate stations Great Whale River, Canada, and Byrd, Antarctica, has been inspected for these fluctuations. From 48 active days (that is, with activity lasting at least 6 h) during the period March–October 1963, seven cases of fluctuation have been found. They occurred between 0500 and 1300 local time, with a mode at about 1100 local time. They are therefore somewhat later in the day than are those seen at Kiruna. Nevertheless, they have the same property of association with the 'slowly varying' type of absorption. The different time of occurrence is probably due simply to the changing diurnal pattern of absorption with magnetic latitude[2], this being 66·6° at Great Whale River and Byrd, and 65·3° at Kiruna. It seems very probable, therefore, that these fluctuations represent the same phenomenon as that reported by Brown.

Of the seven cases, one has a regular sinusoidal form and the others show periodic features with varying degrees of irregularity. The periodicities are in the range 3–16 min. In all cases, the fluctuations are in phase rather than in antiphase at the conjugate stations. A typical example is shown in Fig. 1, which gives the absorption in decibels, slowly varying components having been removed. The general similarity between the two records, in both amplitude and phase, is obvious. There are also some small phase differences, which seem to grow and then decay progressively over several cycles.

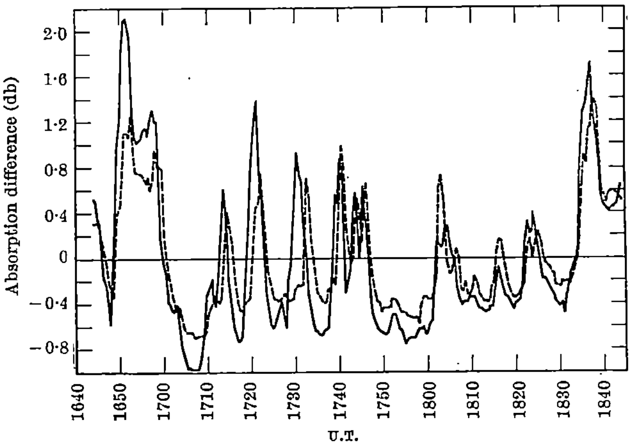

Fig. 1. Detail of absorption at Great Whale River and Byrd on October 14, 1963. The mean trend of the event has been removed. ——, Byrd; - - -, Great Whale River

Our observation presented here appears to be consistent with Brown's suggestion about the cause of the fluctuations. The magnetic observations of Sugiura[3] and Nagata *et al.*[4] indicate that the hydromagnetic disturbance originates near the equatorial plane, whence it propagates along the field-lines to arrive simultaneously in the two conjugate regions. If this propagation of hydromagnetic energy towards the Earth can modulate the flux of precipitated particles, then, provided the phase paths are equal, that modulation should be in phase at conjugate points. The observed periodicities also accord reasonably with Dungey's[5] treatment of hydromagnetic oscillations in the exosphere. From this we should expect the periods of 2·5–8·5 min observed at Kiruna to be scaled up by a factor of about 2·6 at Great Whale River and Byrd. The observed periodicities, 3–16 min, are indeed longer than those at Kiruna, though perhaps not quite as long as expected. On the other hand, our observation does not in itself prove that hydromagnetic waves are the cause of the fluctuations. It only limits the choice to mechanisms acting symmetrically with respect to the equatorial plane.

It is interesting to note that these absorption fluctuations, which are in phase at conjugate points, occur in just that part of the day when the slow fluctuations, which have periods up to 2 h and are in antiphase at conjugate points[6], are least common. This might mean that different parts of the exosphere tend towards different modes of oscillation. However, further phenomena will no doubt come to light before the picture is complete.

The riometers were operated by W. M. McMurtry (Great Whale River) and L. D. Lewis (Byrd). The field operation was made possible through the co-operation of the Canadian Government and the U.S. Navy. The work was financially supported by the National Science Foundation through grant 23788.

PHYSICS

Metastability of Amorphous Structures

IN earlier papers[1–4] we developed a free-volume model for the amorphous phase according to which the liquid and glassy states of a given substance together comprise a single, thermodynamically well-defined phase. In this model the transition to the glass state results ideally from the freezing out of the free volume, and hence the configurational entropy of the liquid[3]. This transition should occur in all classical liquids, including monatomic ones, provided crystallization is by-passed[2]. Implicit in these ideas is the hypothesis that the glassy state is truly metastable and not unstable; consequently, by the Nernst theorem, it would have vanishing entropy at 0° K. For the hypothesis to be true, each microscopic structural unit of the glass must lie at a position of static equilibrium, the totality of which is randomly distributed. If one such structure exists there must be a large number of similar random structures of equal energy. Nevertheless, the entropy of each is zero, because all these structures are mutually inaccessible. One particular structure would be picked out in a given cooling process, and the system would remain in that structure. The increase of entropy on heating back into the liquid state would then occur because the equivalent random structures become mutually accessible[5].

This hypothesis of metastability is supported by some recent observations on model systems and by recent computations of Rahman.

It had been found[6] that a random arrangement of hard spheres will compress to a rigid and apparently amorphous structure (dense random structure) with a unique density (0·86 times that of ideal close packing). The detailed observations of nearest neighbour contacts in this structure carried out by Bernal *et al.*[7] indicate that each sphere is rigidly locked into position within a truly amorphous structure. It follows that the Bernal dense random structure satisfies the condition of mutual inaccessibility of equivalent structures and hence is metastable; it therefore constitutes the prototype of the monatomic glass predicted in our earlier papers. Stillinger, DiMarzio and Kornegay[8] have shown that a random two-dimensional assembly of uniform hard disks also collapses to a rigid dense random structure which they consider to be a model for a two-dimensional glass.

Recently, Rahman[9] carried out machine calculations of the trajectories of a collection of 864 spherical atoms interacting via a 6–12 potential appropriate to argon and held at a density equivalent to that of crystalline argon at 40° K and one atmosphere pressure. Under the conditions of his calculations, he finds that the liquid state of this system can be 'quenched' in a period of 10^{-12} sec to a temperature of 10° K without crystallization. In effect, these calculations of Rahman may be regarded as equivalent to a laboratory experiment in which minute droplets of liquid argon are quenched rapidly. They further confirm the high resistance of amorphous systems, even when monatomic, to the initiation of crystallization.

Inasmuch as the hypothesis of metastability is intuitively most difficult to accept for monatomic systems, we regard these two instances of its correctness as convincing evidence for its general validity.

We thank Dr. A. Rahman for permitting us to refer to his work prior to its publication and for his advice.

Electrical Conduction in Amorphous Films

WHILE carrying out general exploratory work on the electrical properties of vacuum-deposited thin films, an interesting phenomenon was observed in boron layers. Similar effects have since been observed in other materials; however, most of the work so far has been with boron films. The purpose of this communication is to describe the observed phenomenon, leaving the explanation to a later date when more facts have been collected.

The boron layers were deposited by direct electron bombardment in a vacuum of about 10^{-5} mm mercury. An electron beam was focused on an extremely pure boron rod which rested on a carbon pedestal. Every precaution was taken to bombard only the boron and not the pedestal. The carbon pedestal was of spectroscopic grade purity. A beam current of approximately 120 m.amp at a voltage of about 10 kV was found sufficient to obtain a deposition rate of 100–200 Å/min.

The complete sample preparation consisted of first depositing metal electrodes, usually aluminium, in the form of strips (a few mm wide) on an in.^{2} glass substrate. The boron was then deposited on the substrate (at ambient temperature), leaving only the ends of the electrodes free. Finally, the top electrodes were deposited using the same mask as the first electrodes, but rotated 90°. This formed a cross-grid structure with boron separating each cross-over. The electrodes were deposited in a different chamber from the boron in order to prevent contamination. This procedure allowed oxidation of the bottom electrodes when the substrates were exposed to air. However, since gold electrodes yielded similar results and no asymmetry was observed in the samples, it is not believed that oxidation plays a part in the effect. During each step of sample preparation appropriate vacuum outgassing was conducted.

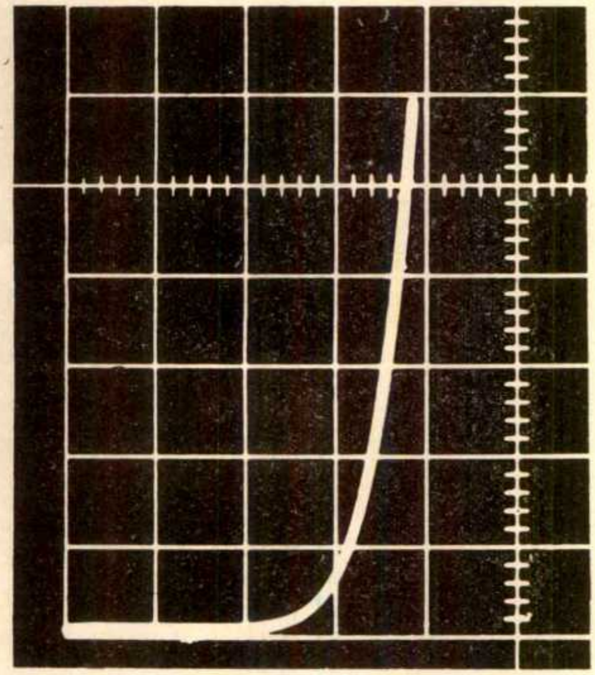

Fig. 1. Oscilloscope trace showing current-voltage relationship in a thin boron film (Sample No. 74). Scales: vertical, 0·5 m.amp/div.; horizontal, 10 V/div.

A typical current-voltage oscilloscope trace of a boron sample is shown in Fig. 1. Reversal of the voltage produces the same trace in the opposite direction, indicating that the curves are completely symmetrical about the origin. The current density through the sample can be described by the following relation:

$$i = KV^n \qquad (1)$$

The constants K and n vary considerably between samples. At very low voltages, depending on the sample, the currents tended to ohmic behaviour. Some typical values of K and n are shown in Table 1 along with appropriate physical parameters. K is calculated to yield the current density in amp/cm^2. As can be seen from Table 1, n is larger than that usually found in symmetrical varistors[1]. Sample No. 76, listed in Table 1, which used gold alloy electrodes showed similar results to the aluminium electroded samples.

Table 1. PARAMETERS OF BORON FILM SAMPLES

Boron film sample No.	n	K	Thickness (Å)	Electrodes	Electrode area
28	6·2	$2·2 \times 10^{-10}$	2100	Aluminium	$7·7 \times 10^{-3}$ cm^2
34	7·2	$1·0 \times 10^{-11}$	1300	Aluminium	7·7
53	6·6	$8·1 \times 10^{-12}$	4500	Nichrome	7·7
64	8·2	$2·6 \times 10^{-13}$	2400	Nichrome	7·7
74	8·3	$9·5 \times 10^{-14}$	2700	Aluminium	2·0
76	6·1	$4·3 \times 10^{-9}$	2700	50% Au–50% Al (alloy)	0·4

A planar electrode configuration was examined in which the boron was placed between two deposited nichrome tabs separated by about 13μ. The same general behaviour was observed. This geometry enabled the examination of the photoconductive properties of the layers. The boron films showed some photoconductivity when exposed to a tungsten light source, and the magnitude of the photoconductivity was directly dependent on the voltage applied across the sample.

Optical transmission data revealed a band edge at approximately 1·6 eV. The sample resistance increased with decreasing temperature; however, the relationship between temperature and the constants n and K has not yet been determined. An exact dependency on film thickness has likewise not been found. This is probably due to the strong dependence on purity and deposition parameters which masks other effects.

The sample purity and structure seemed to play a major part in determining the constants K and n of equation (1). The samples which gave the highest n were made from the purest boron obtainable (L. Light and Co., Ltd., Colnbrook, England). Samples made from impure source material yielded very poor results and, if the material was less than 99·99 per cent pure, the effect was not observed at all. X-ray diffraction did not reveal any crystal structure and it must be assumed that the films are completely amorphous. Films deposited at higher temperature in which some crystal structure was discernible did not show the observed non-linear current-voltage relationship.

A similar, but less-pronounced, effect has been observed in amorphous germanium and silicon films formed in the same manner. The effect likewise disappears when the films are heated and become crystalline in structure. Based on the foregoing observations it is apparent that the phenomenon is related to the amorphous nature of the layers. These amorphous semiconductor films have high resistivities and low charge carrier mobilities, enabling a high field strength to be maintained across them. This high field probably causes the observed effect either through an increase in the mobility, and/or the number of charge carriers in the sample. It is hoped that continued work will reveal the exact nature of the behaviour and will also lead to a better understanding of the properties of amorphous semiconducting films.

Load Discontinuity Method for Pressure Calibration : the Tetrahedral Anvil Apparatus below 25 Kilobars

PRESSURES in ultra-high pressure apparatus of the belt or anvil[1] types are commonly inferred from a subsidiary load/pressure calibration using the well-known resistance discontinuities in bismuth at 25·4 kilobars[2], in thallium at 36·7 kb[2] and in barium at 59 kb[3]. Possible uncertainties of this method are associated with: (*a*) variations in the anvil[4] and test-cell materials[5]; (*b*) the influence of sample geometry[6]; (c) the influence of temperature, particularly when generated within the test-cell[1]; (*d*) the rather wide region between 0 and 25·4 kb for which no very suitable resistance transition is yet available. In this communication a load discontinuity method is described which extends load/pressure calibration for ultra-high pressure apparatus. It is applied here to a ¾-in. edge tetrahedral unit of the N.B.S. type[1].

For a normal pressure calibration the wires of bismuth, thallium or barium are surrounded by a sleeve of low shear strength material, typically silver chloride. This minimizes the effects of stress gradients, non-hydrostatic stresses and deformation within the pyrophyllite, which is generally used as the solid pressure transmitting material in high-pressure test-cells. Curve *A* of Fig. 1 shows a typical load/resistance relation for a bismuth wire in a silver chloride sleeve: the sample was mounted between opposite faces of the tetrahedron as shown, and electrical contact was made directly to the anvil faces via soft copper end plugs. The anvils, of cemented tungsten carbide with 6 per cent cobalt binder, were painted with jeweller's rouge. Fig. 1 is taken from an *XY* recorder trace; the load signal was derived from a strain gauge load cell, and the resistance from the potential difference along the wire at constant current. Load was increased steadily at about 1 ton/min in the experiment, using a continuously pumped hydraulic press. Bismuth shows a rapid increase of resistance with pressure up to the onset of the transition at 25·4 kb. Curve *B* shows the corresponding load/pressure relation, when the silver chloride is replaced by a pressure-equalizing sleeve made from cuprous iodide: this has a rapid reversible transition at 14·1 kb at 20° C (ref. 7). In this case the monotonic resistance increase of the bismuth has been interrupted by a horizontal *t*, and, at the same time, the 25·4 kb transition has been displaced to higher loads, by an amount approximately equal to *t*. Both effects are due to the volume change accompanying the transition in the cuprous iodide sleeve (in this case ~ 0·006 cm^3/g)[7], and *t* represents the load necessary to 'take up' this change. It will be noted that this effect will be most obvious in high-pressure apparatus of the belt or anvil types, where there is a definite relation (through the compressibility of the test-cell) between the test-cell volume, the applied load and the pressure generated. Silver chloride itself has a transition at ~ 13 kb[7]. This transition, however, is sluggish and has only a small volume change (0·0001 cm^3/g); it has not been detected in these experiments.

A load/pressure relation for the tetrahedral anvil apparatus was obtained by using the following sleeves with suitable reversible volume transitions in the 0–25 kb range: potassium nitrite at 6·2 kb[8], silver perchlorate at 7·5 kb[7], cuprous iodide (as aforementioned) at 14·1 kb, and potassium bromide at 18 kb[9]. Except for the last-mentioned, which was machined directly from the solid, samples were precompacted from the powder, using a simple die with a removable core to provide the hole for the wire specimen. Bismuth was used as the sensing resistance in each case; there is no reason in principle why other materials with an appreciable pressure coefficient of resistance (or indeed of another suitable property) might not be used. Fig. 2 shows the load/pressure relationship obtained for the various sleeves: the beginning of the horizontal was taken in each case to indicate attainment of the appropriate transition pressure. Each point in Fig. 2 is a mean of three points except for cuprous iodide with four. Successive runs were repeatable and the estimated load error is ± 1·0 ton. With the exception of one run in silver perchlorate there was little evidence of negative slope in the interval *t*, which would indicate metastability of the low-pressure phase. Furthermore, the slopes of the resistance/load curves prior to the transitions (Fig. 1) were very similar to that for silver chloride, so that differences in the compressibilities of the sleeve materials do not appear to be important in this pressure range.

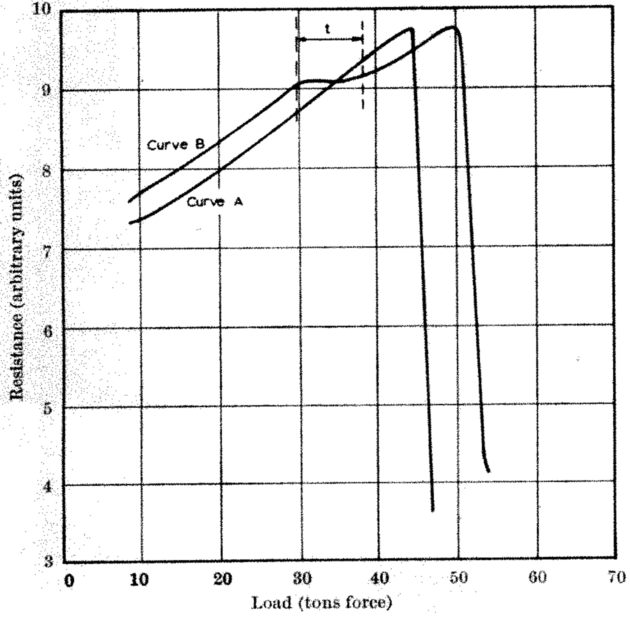

Fig. 1. Pressure variation of resistance of bismuth wire in sleeves of: *A*, silver chloride; *B*, cuprous iodide with a transition at 14·1 kb

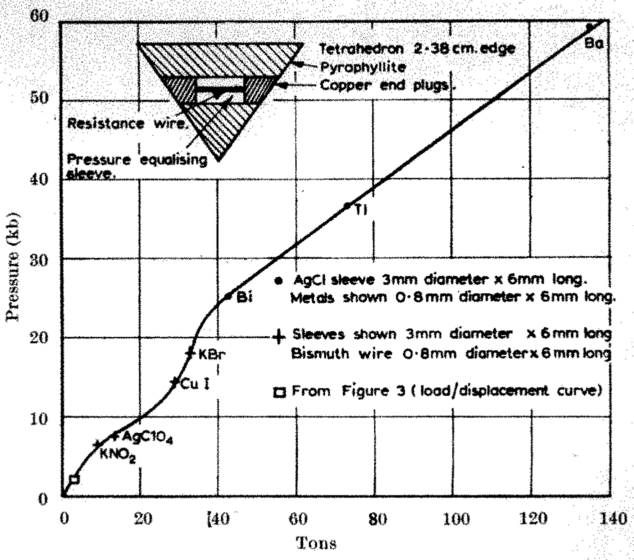

Fig. 2. Load/pressure curve for 3/4 in. edge N.B.S. type tetrahedral anvil apparatus with (insert) tetrahedron assembly

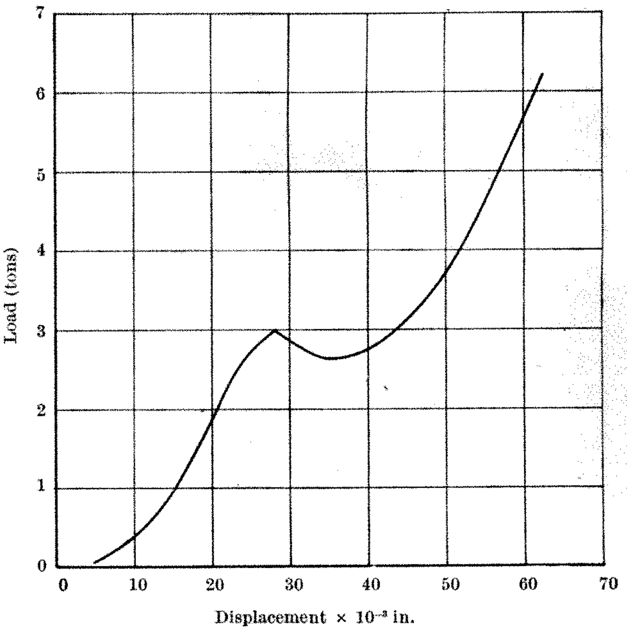

Fig. 3. Load versus displacement; pyrophyllite tetrahedron in N.B.S. tetrahedral anvil apparatus

Further information on the pressure generation in the tetrahedral apparatus can be derived from Fig. 3, which shows the load/displacement characteristic during the initial stages of compression of a plain pyrophyllite tetrahedron, displacement being measured by means of an inductive transducer mounted between the top anvil and the base plate of the apparatus. This type of curve, with load rising to a maximum, a fall to lower value and a subsequent rise, is typical, as might be expected, of extrusion in the presence of friction[10]. It is reasonable to suppose that the observed maximum in the load at 3·0 tons corresponds to the beginning of the extrusion process which forms the compressible gaskets: at this load the mean pressure on the anvil faces is 1·8 kb. This point is plotted in Fig. 2.

The conventionally obtained bismuth, thallium and barium points are also plotted, and it may be seen that the combined curve obtained by these methods has a fairly complicated shape. It may be divided into three regions: (*a*) the initial pressure rise, with a slow falling off in slope up to ~ 12 kb; (*b*) a rapid increase in slope between this pressure and 23–24 kb; (*c*) a fall off thereafter to a fairly linear relation up to the barium point. While it is possible that metastability of the low-pressure phases could have affected the transition loads, we believe that the straightforward and consistent experimental results obtained make this unlikely. Fig. 2 then indicates that the load/pressure characteristic for the N.B.S. type tetrahedral anvil apparatus is very similar to that obtained by Litster and Benedek[11] for a 'belt' type apparatus, using the pressure variation of the ^{57}Fe nuclear resonance frequency.

The complicated shape of both curves is undoubtedly related to the precise mechanism of pressure generation.

I thank M. Dyke, who performed much of the experimental work. I also thank K. Ashcroft and C. H. L. Goodman for discussions, and the management of these laboratories for permission to publish this communication.

CRYSTALLOGRAPHY

Two New Binary Chromium Oxides

WELL-DEVELOPED black crystals of two chromium oxides (*A* and *B*) with composition between CrO_3 and CrO_2 have been obtained by heating CrO_3 in a high-pressure autoclave at 200°–300° C. The oxygen pressure was 1·5–3 kilobars.

Single crystal photographs of substance *A* indicate the Laue symmetry *mmm*, and the conditions limiting possible reflexions suggest the space group *Pbcn* (No. 60). The unit cell dimensions of *A* derived from single crystal and powder photographs are:

$$a = 12{\cdot}04\ \text{Å};\ b = 8{\cdot}21\ \text{Å};\ c = 8{\cdot}18\ \text{Å};\ V = 808\ \text{Å}^3$$

The observed density, 3·68 g cm^{-3}, corresponds to a formula weight of 1,790 per unit cell, suggesting a cell content of 4 Cr_5O_{12} (1808).

The Laue symmetry of the substance *B* was also found to be *mmm*, and the missing spectra were those characteristic of the space groups *Cmcm* (No. 63), *C2cm* (No. 40) and $Cmc2_1$ (No. 36).

The unit cell dimensions of *B* as obtained from single crystal and powder photographs are:

$$a = 8{\cdot}47\ \text{Å};\ b = 12{\cdot}88\ \text{Å};\ c = 10{\cdot}09\ \text{Å};\ V = 1101\ \text{Å}^3$$

The observed density, 3·34 g cm^{-3}, corresponds to a formula weight of 2,210 per unit cell, suggesting a possible cell content of 12 Cr_2O_5 (2208) or 8 Cr_3O_8 (2278).

The powder patterns of *A* and *B* are distinctly different from those reported earlier[1] for specimens with the gross compositions ~ Cr_3O_8 and ~ Cr_2O_5.

Crystal structure determinations of these two new chromium oxides as well as further preparative investigations in this field are in progress.

This investigation forms part of a research programme on the crystal chemistry of chromium compounds, which is supported by the Swedish Natural Science Research Council.

METALLURGY

Role of Silica in the Oxidation Resistance of Molybdenum Disilicide

MOLYBDENUM disilicide is of particular importance in the field of high-temperature materials, both as a structural material in its own right and as an oxidation resistant coating for molybdenum alloys. Apart from having a high melting point of 2,000° C (ref. 1) and good oxidation resistance up to 1,700° C, $MoSi_2$ possesses high-temperature mechanical properties which make it adequate for many applications under static high-temperature oxidizing conditions[2].

However, a relatively high elastic modulus coupled with low thermal conductivity and high thermal expansion render it prone to crack on thermal cycling, so that a molybdenum test-piece silicided by pack cementation at

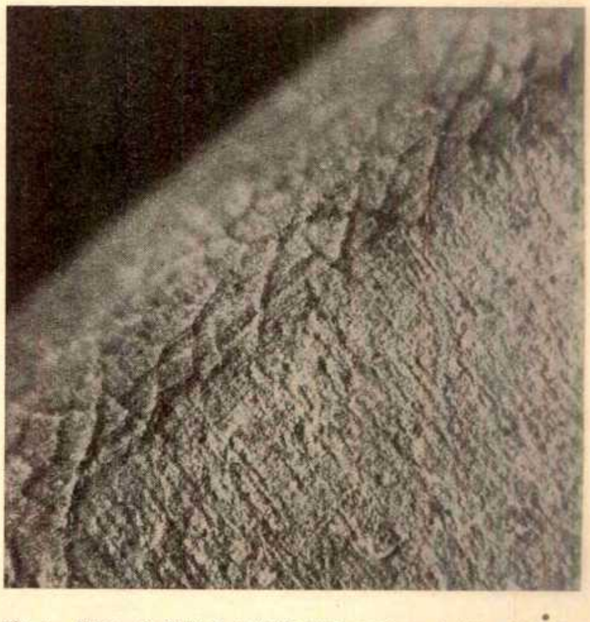

Fig. 1. Edge of silicided molybdenum specimen (×30) which has craze-cracked as a result of thermal cycling from 1,100° C to room temperature

1,100° C (ref. 3) will rapidly 'craze' if repeatedly thermally cycled to this temperature (Fig. 1).

Although such cracks are obviously detrimental to oxidation protection, an interesting and puzzling feature is that the cracking of a $MoSi_2$ coating does not necessarily result in failure of the part. We believe that this must be largely due to the secondary protection afforded by lower silicides of molybdenum which exist as an intermediate system between disilicide and substrate in most as-prepared coatings or are later developed by thermal diffusion (Fig. 2). This intermediate system, which may be identified by X-ray analysis as compounded of Mo_5Si_3 and Mo_3Si, is not oxidation resistant and decomposes on heating to silica. On theoretical grounds this should occur with a large volume increase and, in fact, if a sectioned specimen is heated in air at 650° C and observed microscopically, the decomposition product is seen to protrude from the surface as a siliceous ridge (Fig. 3). At this temperature the silica produced occurs as a low-density frit of loosely bound particles, and this may well exaggerate the volume increase, but it is considered that a similar mechanism operating at higher temperatures will root-fill any crack that develops in the outer $MoSi_2$ coating and hence arrest further ingress of oxygen (Fig. 4).

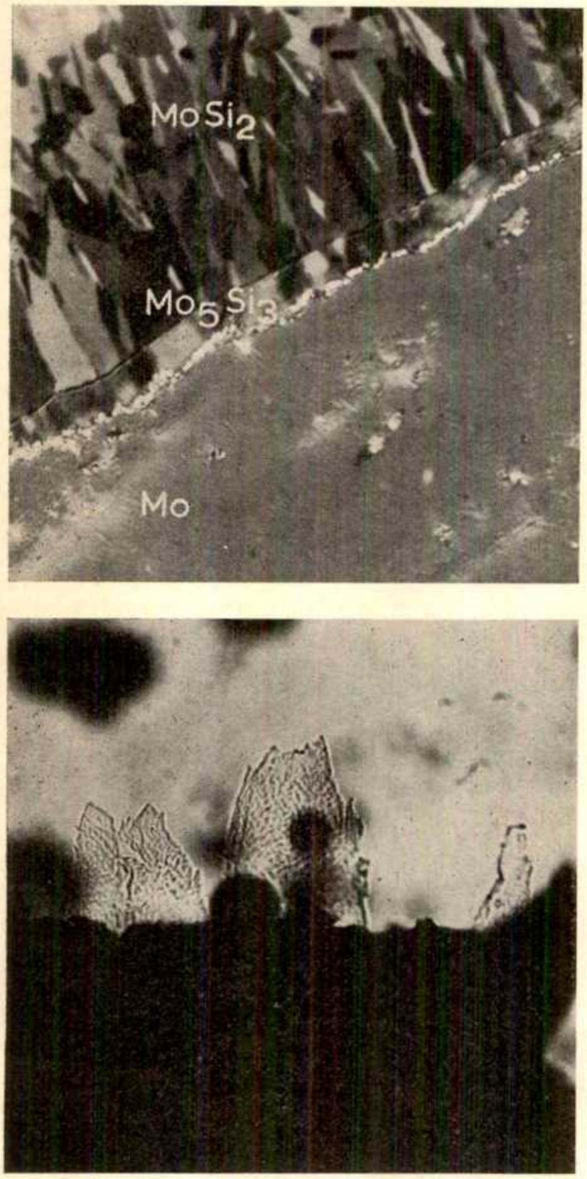

Fig. 2. Above, cross-section of silicided molybdenum specimen (× 1,500) showing the columnar outer $MoSi_2$ coating superimposed on a narrower intermediate layer of Mo_5Si_3. Below, the specimen has been lightly etched with nitric acid and the very narrow bright region between the Mo_5Si_3 and molybdenum substrate probably represents a thin oxidized Mo_3Si zone. Prolonged oxidation in acid causes the whole intermediate system to decompose to silica gel and to project from the surface (× 90)

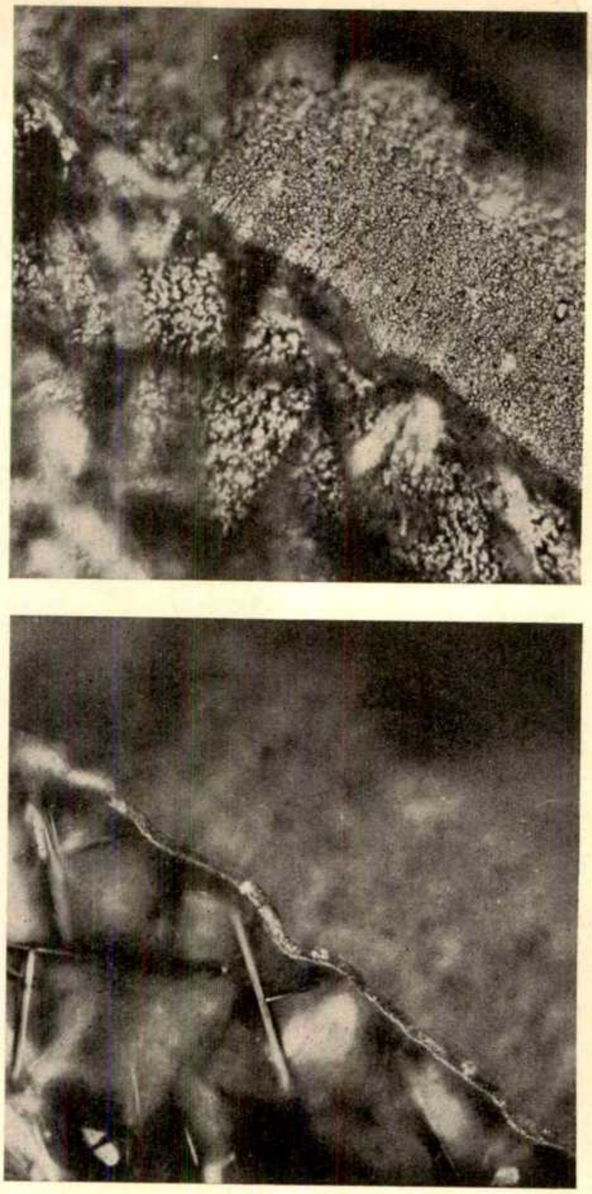

Fig. 3. Cross-section of a silicided molybdenum specimen (× 750) oxidized in air at 650° C. Above, the microscope has been focused on the plane of the specimen; below, the photograph shows detail 5μ above the plane and demonstrates the expansion of the intermediate layer of Mo_5Si_3 on oxidation. Crystals of MoO_3 are also evident

It is possible that at higher temperatures a low-melting mixture of MoO_3 and SiO_2 forms initially and that this flows before losing MoO_3 by volatilization and finally solidifying. This would substantially aid the crack-filling process, and it is noteworthy that a particularly effective coating results if molybdenum boride is laid down between the silicide and metal substrate. This composite coating, which will survive many thousand thermal cycles without failure, soon becomes covered with a system of cracks from which siliceous material erupts and later devitrifies to cristobalite (Fig. 5). It is probable in this case that the exaggerated crack-filling process results from the fluxing action of boron oxides derived from molybdenum boride.

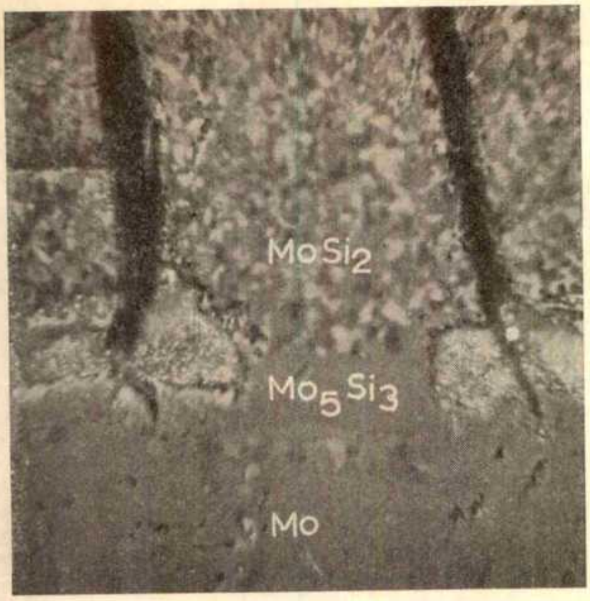

Fig. 4. Cross-section of a silicide multilayer on molybdenum (× 720). The outer MoSi$_2$ and Mo$_5$Si$_3$ layers have cracked and air has found its way to the intermediate system to decompose the Mo$_5$Si$_3$ layer to silica

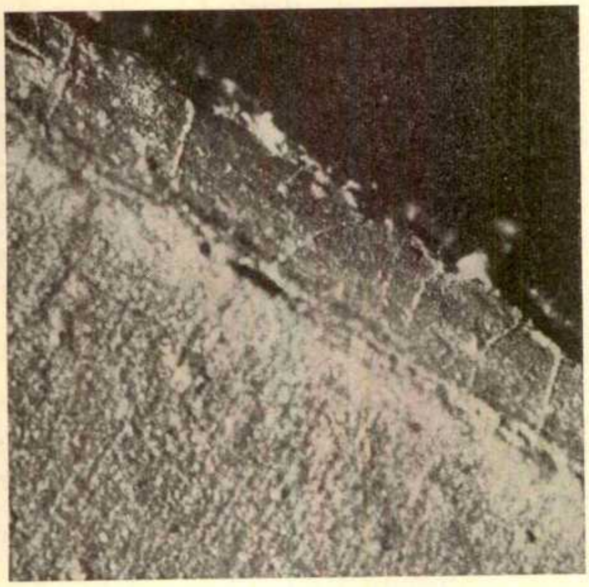

Fig. 5. Edge of silicided molybdenum specimen (× 30) which has had molybdenum boride located at the interface between the MoSi$_2$ and the molybdenum substrate. The fluxing action of oxides of boron has caused silica from the decomposition of the Mo$_5$Si$_3$ intermediate layer to erupt to the surface through the cracks in the MoSi$_2$

A mechanism involving oxidation of Mo$_5$Si$_3$ may also explain the unique oxidation resistance of molybdenum disilicide among the silicides at temperature extremes of up to 1,700° C. Molybdenum disilicide develops an appreciable vapour pressure as this temperature is approached[4] and in vacuum has been shown to lose silicon to acquire a surface layer of Mo$_5$Si$_3$ (ref. 1). In air this product will decompose and expand to silica as soon as it is formed and the disilicide will rapidly become covered with a protective siliceous crust.

The unique resistance of molybdenum disilicide to oxidation is presumably due to the fact that the metal oxide MoO$_3$ is volatile and rapidly evolves to leave a solid residue of silica melting only above 1,700° C. This is apparently substantiated by the fact that the introduction of metal oxides to the coating has a disadvantageous effect on oxidation resistance, probably as a result of persistent fluxing action[5].

GEOCHEMISTRY

Palæoclimatic Significance of δ-Oxygen-18-time Trends observed by Oxygen Isotopic Analysis of Freshwater Limestones

AFTER McCrea[1] and Epstein *et al.*[2] established the carbonate–water palæotemperature technique whereby the temperature of calcium carbonate precipitation can be determined by measuring the oxygen-18 content of the calcite, this tool has been widely utilized by a large number of workers for marine carbonates ranging in age from early Mesozoic to the present. Since the fractionation factor, that is, the isotopic composition of calcite divided by that of sea-water, is temperature dependent, deposition temperatures can be determined by: (1) measuring the $^{18}O/^{16}O$ ratio of ancient carbonate; (2) assuming a value for the isotopic composition of sea-water at that time.

So far, this technique has not been applied to fresh-water carbonates, presumably because of large present-day variations in the isotopic composition of fresh-water, shown, for example, by the data of Dansgaard[3], and Epstein and Mayeda[4]. If the $^{18}O/^{16}O$ ratio of fresh-water varied to this extent in large ancient lakes, temperatures determined by this method would be meaningless.

This need not be the case, however, at times when ice caps were non-existent, presumably over much of geological time. The isotopic composition of meteoritic water formed by the evaporation of sea-water is approximately −7 per mil. relative to the mean ocean water standard, and Epstein and Mayeda claim that isotopic fractionation which changes the oxygen-18 content of meteoritic water from about −7 per mil. to about −20 per mil. occurs in areas close to and possibly in the permanently glaciated regions. These authors further suggest that precipitation over the larger part of the Earth has an oxygen-18 content similar to that resulting from the initial evaporation of sea-water from the surface of the ocean, that is, −7 per mil.

Thus, in times of non-glaciation, the isotopic composition of large bodies of fresh water, especially in latitudes where calcium carbonate precipitation is possible, should not be a large variable. If enough samples of fresh-water limestones are used to suppress random errors or variations, it should be possible to determine palæotemperatures for these carbonates. Moreover, since these bodies of water are much smaller than the oceans, the response of water temperature to changes in climate are more rapid. Hence, fresh-water carbonate sequences may provide very detailed climatological trends and serve as sensitive palæoclimatic indicators.

In this light, a select collection of 157 samples of fresh-water limestones assembled by Keith and Weber[5] might be examined. Almost all these specimens are from North American localities, and range in age from Devonian to the present. Each sample was identified on the basis of fresh-water fossils and was analysed for $^{18}O/^{16}O$ ratio in

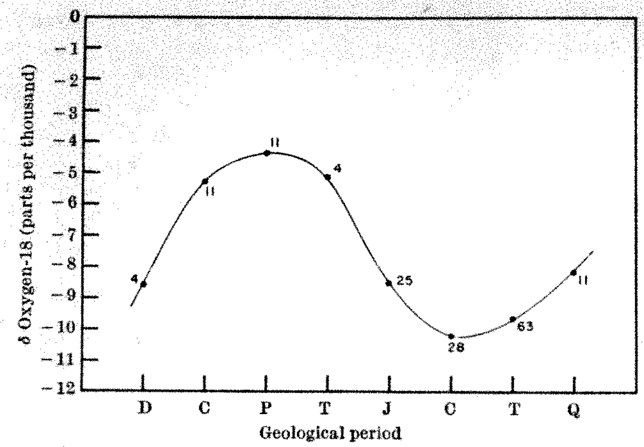

Fig. 1

duplicate using a 6 in., 60° sector mass spectrometer with isotope ratio recording apparatus. Grouped according to age, mean δ-oxygen-18 values relative to the Chicago P.D.B. standard, with the standard deviation given in brackets, are: Devonian −8·57 (1·3), Pennsylvanian −5·25 (1·6), Permian −4·36 (3·5), Triassic −5·12 (0·91), Jurassic −8·52 (3·0), Cretaceous −10·22 (3·5), Tertiary −9·65 (4·5), and Quaternary −8·15 (2·1). The results illustrated in Fig. 1 appear to generate a sinusoidal curve with $^{18}O/^{16}O$ maxima in the periods Permo-Carboniferous and Quaternary, and a minimum in the Cretaceous. The striking fit of the mean δ-oxygen-18 values to the curve shown in Fig. 1, the magnitude of the difference (about 6 per mil.) between the maximum and the minimum, and the occurrence of relatively high oxygen-18 contents in the carbonates precipitated during geological periods (Permo-Carboniferous and Quaternary) when glaciation was known to have occurred, strongly suggest that the data based on 314 analyses of 157 samples reflect temperature differences in large lakes located in central North America.

There are a number of variables on which the isotopic composition of fresh-water carbonate depends; these are discussed by Keith and Weber[5]. If the effects of some of these variables can be eliminated, for example, by proper sampling, random variation should cancel if enough samples are taken.

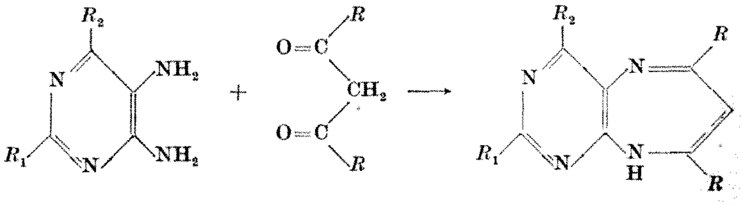
CHEMISTRY

Structural Investigation of 4-[(4-Amino-5-pyrimidinyl)imino]-2-penten-2-ol

As part of a continuing programme of synthesis of condensed pyrimidine ring systems as potential antimetabolites and antitumour agents, the preparation of the hitherto unreported 1,5-pyrimido[4,5-*b*]-diazepine ring system (I) was undertaken in these laboratories[1]. This ring system is analogous to the 1,5-benzodiazepines extensively examined by a number of investigators[2-8]. The preparation of the pyrimidodiazepines (I) was attempted by condensation of 4,5-diaminopyrimidine derivatives with β-diketones, as in the synthesis of the corresponding 1,5-benzodiazepines



I

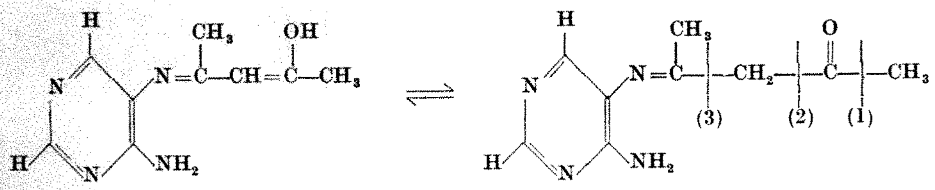
Reaction of a number of substituted 4,5-diaminopyrimidines with β-diketones under neutral or weakly acidic conditions afforded good yields of yellowish reaction products that are soluble in non-polar solvents and crystallize from benzene or methanol. These compounds possess definite melting-points and display two ultraviolet absorption maxima at *p*H 10, the longer wavelength peak being in the range 305–315 mμ. The infra-red spectra show sharp bands in the NH and OH regions and exhibit no carbonyl absorption.

The elemental analyses of the condensation products consistently show the presence of the elements of water, which could not be shown to be water of crystallization by the Karl–Fischer test. Therefore, an investigation of structure was undertaken in order to determine whether the compounds are hydrates of structure I or isomeric forms with covalent carbon–oxygen bonds, such as II–IV. For this purpose the simplest derivative was examined, namely, the condensation product of 4,5-diaminopyrimidine and 2,4-pentanedione.

4,5-Diaminopyrimidine (0·05 mole) was condensed with 2,4-pentanedione (0·055 mole) in 50 ml. of refluxing absolute methanol for 9 h. After removal of solvent, the residual reaction mixture was crystallized from methanol with the aid of activated carbon and a 61 per cent yield of off-white crystalline material (compound *A*) was obtained. Sublimation at 120°–140° (0·005 mm) afforded analytically pure, off-white monoclinic needles, m.p. 180°–182° dec., which are photosensitive and easily oxidizable. (Calc. for $C_9H_{12}N_4O$: C, 56·2; H, 6·3; N, 29·1; found: C, 56·3; H, 6·4 N, 28·9.)

The ultra-violet spectrum is consistent with extended conjugation involving the pyrimidine ring: λ_{max} in mμ (ε): *p*H 1–280 (10,700); *p*H 10–231 (9,600), 314 (19,100); EtOH – 232 (10,300), 314 (16,400). In the infra-red the principal features are λ_{max}^{KBr} 3·03μ (OH, NH); 3·20μ (CH); 6·05, 6·19, 6·35, and 6·70μ (C=N, C=C, pyrimidine ring). No carbonyl bands were seen either in KBr or in chloroform.

Inasmuch as the foregoing chemical and physical properties do not permit a definite assignment of structure, the compound was investigated by nuclear magnetic resonance spectroscopy, mass spectrometry, and X-ray structure analysis. The nuclear magnetic resonance spectrum fails to support structure I and is consistent with the open-chain structure II. (The isomer of II with a free amino group at pyrimidine position 5 is unlikely to have formed. Since the 5-amino group of 4,5-diaminopyrimidine has a greater degree of nucleophilic character than the 4-amino group, involvement of the 5-amino group in Schiff's base formation is the preferred reaction[9].) The nuclear magnetic resonance spectrum in deuterochloroform, taken with a Varian *A*-60 spectrometer with tetramethylsilane as the internal reference, shows two dissimilar methyl groups at 8·2τ (3 hydrogens) and 8·0τ (3 hydrogens), and no methylene group in the 6·0–6·5τ region. One enolic hydrogen at −1·8τ, one vinyl hydrogen at 4·9τ, and a broad peak at 4·3τ (2 hydrogens), corresponding to a primary amino group, are observed. The two pyrimidine ring hydrogens appear at 2·2 and 1·9τ. Both peaks at −1·8 and 4·3τ exchanged rapidly with deuterium when the compound was treated with deuterated acetic acid (d_4), and the vinyl hydrogen peak at 4·9τ exchanged slowly. Except for the absence of the

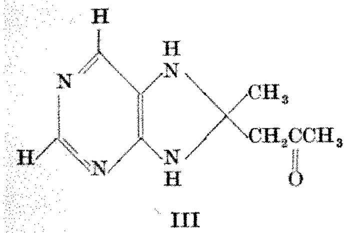


II ⇌ II*a*

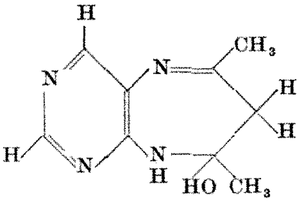
methylene band, the nuclear magnetic resonance spectrum of the non-nitrogenous side-chain of the molecule is generally similar to that of 2,4-pentanedione[10].

The mass spectrum (determined with a G.E.C. 21–103*C* mass spectrometer, equipped with a heated inlet system, operated at 170°; ionization potential 70 eV; ionizing current 50 μamp) of this compound indicates the molecular weight to be 192, rather than 174 which would correspond to the anhydrous ring system I. Furthermore, the successive elimination of mass units 15, 43 and 57, along with the appearance of a strong peak at m/e 43 (CH_3CO^+), is consistent with fragmentation of the side-chain of the uncyclized structure II*a*, tautomeric with the enolic form II. At the low pressure prevailing in the mass spectrometer, the less associated keto form II*a* is evidently favoured and the side-chain undergoes the indicated cleavages at (1), (2), and (3).

Major mass ions (m/e)	Fragments lost	Observed peaks
M	None	192
M-15	(1) $CH_3\cdot$	177
M-43	(2) $CH_3CO\cdot$	149
M-57	(3) $CH_3COCH_2\cdot$	135



III



IV

It is possible, then, to reject structures I, III and IV for compound *A* on the basis of the combined ultra-violet, infra-red, nuclear magnetic resonance, and mass spectral data. The X-ray analysis recently performed by Yannoni and Silverman[11] provides final confirmation of structure II (Fig. 1) and proves that the 5-amino group of 4,5-diaminopyrimidine did indeed participate in the reaction. The X-ray analysis establishes the positions of the heavy atoms in the molecule. The molecule lies in two planes and the crystal structure is characterized by an extensive network of hydrogen bonds. Cyclization to diazepine structure I or IV is rendered unlikely because, in the solid state, the primary amino group of the pyrimidine ring not only lies in a separate plane but is also far removed from the oxygen function. The X-ray analysis does not clearly indicate the enol (II): keto (II*a*) tautomeric ratio in the crystal state.

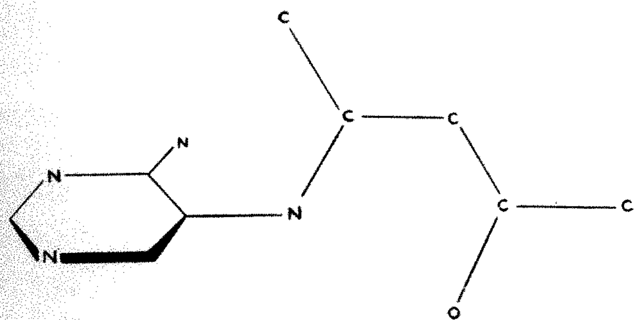


Fig. 1. Molecular structure of 4-[(4-amino-5-pyrimidinyl)imino]-2-penten-2-ol (ref. 11)

In summary, compound *A* has been assigned the structure 4-[(4-amino-5-pyrimidinyl)imino]-2-penten-2-ol (II). All the chemical, physical and spectral data presented are consistent with this assignment, except for the existence of the keto tautomer II*a* in the vapour phase during mass spectrometry and in the crystal state.

We thank Dr. K. Biemann, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Mass., for making available the mass spectrometric facilities in his laboratory; Dr. B. C. Das, of the same Department, for carrying out and interpreting the mass spectrometric analysis; and Drs. N. F. Yannoni and J. Silverman, of the Space Physics Laboratory, U.S. Air Force Cambridge Research Laboratories, Bedford, Massachusetts, for collaborating with us and keeping us informed on the status of the X-ray structure analysis.

Pentasulphur Triimides: Completion of a Class of Cyclic Sulphur Imides

AMONG the compounds theoretically obtainable by replacing sulphur atoms in the octasulphur ring by imino groups, heptasulphur imide and tetrasulphur tetraimide have long been known. Last year the 1–3, 1–4 and 1–5 isomers of hexasulphur diimide were reported independently by Tavs, Schultze-Steinen and Colchester[1], and by one of us[2], and we have since confirmed the structures proposed in the latter reference by measurement of dipole moments[3]. Excluding compounds with adjacent imino groups, none of which is known, there remained to be made only two sulphur imides derived from octasulphur in its normal 'crown' conformation, namely, the 1–3–5 and 1–4–6 isomers of pentasulphur triimide. We now report the preparation of two compounds which we think are these.

The crude reaction product from 420 ml. of disulphur dichloride and ammonia in formdimethylamide[4] was extracted with diethyl ether[1], which took up the sulphur imides. The diimides and triimides were concentrated and separated from the bulk of the heptasulphur imide by fractional crystallization. They were then isolated by chromatography on silica gel, eluting at first with carbon disulphide.

1·35 g of the compound thought to be 1–4–6 pentasulphur triimide came off at $R_F \sim 0·16$, immediately after the last (1–3) diimide. It formed long colourless needles, m.p. 131° (decomp.) (found S, 78·3 per cent; N, 21·1 per cent; H, 1·45 per cent; m.wt. (cryoscopic in benzene) 180; calc. for $S_5N_3H_3$, S, 78·0 per cent; N, 20·5 per cent; H, 1·46 per cent; mol. wt. 205). The solubility in carbon disulphide at 18° was 0·049 molal. The saturated solution in a 0·2 mm cell gave strong infra-red bands at 3·01μ (*OD* 0·21), at 11·99μ (*OD* 0·26) and at 12·28μ (*OD* 0·41). The dipole moment in carbon disulphide was difficult to measure accurately owing to association, but approached a value of 1·0 ± 0·3 Debye units with diminishing concentration; the value calculated by vector addition, assuming that each imino group contributes 1·28 Debye units (our measurement of the moment of heptasulphur imide) is 1·4 Debye units.

The other isomer had an R_F of only about 0·09 in carbon disulphide; it was more quickly eluted by changing the solvent to 5 : 2 carbon disulphide–benzene. 0·33 g of colourless rhombs, m.p. 124° (decomp.), were obtained (found S, 78·4 per cent; N, 19·9 per cent; H, 1·57 per cent; m.wt. 210 (cryoscopic in tertiary butanol)). The solubility in carbon disulphide was only 0·008 molal at 18°. The saturated solution in a 0·2 mm cell gave infra-red bands at 3·00μ (*OD* 0·03), at 11·82μ (*OD* 0·04) and at 12·12μ (*OD* 0·07). The dipole moment, in carbon disulphide solution, was also difficult to measure because of the small solubility, but the value found, 2·8 ± 0·6 Debye units, corresponded with the calculated value of 3·0 Debye units for 1–3–5 pentasulphur triimide.

Note added in proof. We have recently heard that Dr. H. Tavs also made the presumed 1-4-6-triimide in unpublished work.

BIOCHEMISTRY

Magneto-optical Rotation Spectra of Cytochrome c

MANY spectroscopic investigations have been reported on cytochrome *c* in defining its role in biochemical electron transport systems[1,2]. These include the ultra-violet and visible absorption measurements of Keilin and Hartree[3] and the optical rotatory dispersion (ORD) data of Eichorn and Cairns[4]. In this laboratory, we have been investigating the application of the new technique of magneto-optical rotation spectroscopy[5] to the examination of different oxidation states of the cytochrome *c* molecule. In this type of measurement, the optical rotations induced by an external magnetic field (Faraday effect) are obtained as a function of wave-length to provide a magneto-optical rotation (MOR) spectrum. The results for cytochrome *c* (Figs. 1–4) are quite pronounced and show large changes with the oxidation state of the molecule.

The MOR spectra were measured for aqueous solutions (essentially the same results were obtained in 0·01 M *p*H 7 phosphate buffer) in a 1-cm cell at a 10,000-gauss field and corrected for the background natural optical activity of the molecule, measured in the absence of a magnetic field. The reduced cytochrome *c* samples were commercial grade preparations (Nutritional Biochemicals, Inc., Cleveland, Ohio) from beef heart muscle. The oxidized samples were prepared by oxidation of the reduced form with potassium ferricyanide and purified by dialysis for four days at 4° C to remove excess salts and by-products. The results in Figs. 1–4 show the plot of specific magnetic rotation, as defined by equation (1), as a function of the wave-length in mμ:

$$[\alpha]^M_{sp} = \frac{\theta}{lc}\left(\frac{10,000}{H}\right) \qquad (1)$$

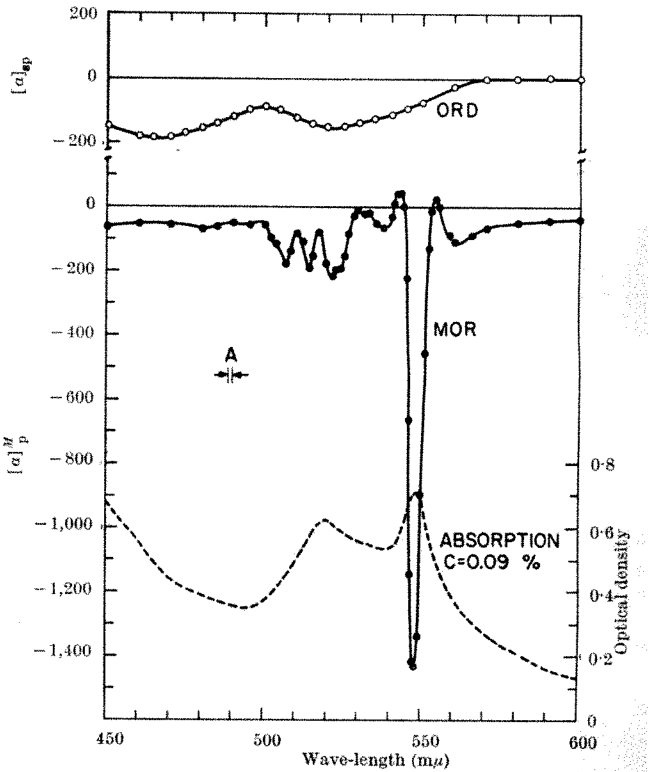

Fig. 1. MOR and ORD spectra of reduced cytochrome *c* at 23° C in water $[\alpha]^M_{sp}$, specific magnetic rotation; *A*, monochromator band pass

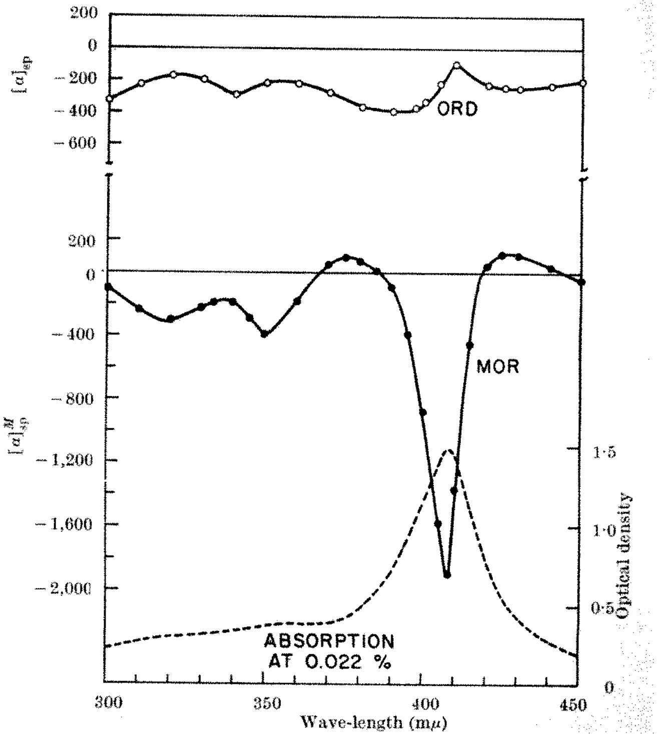

Fig. 2. MOR and ORD spectra of reduced cytochrome *c* at the Soret band region in water at 23° C

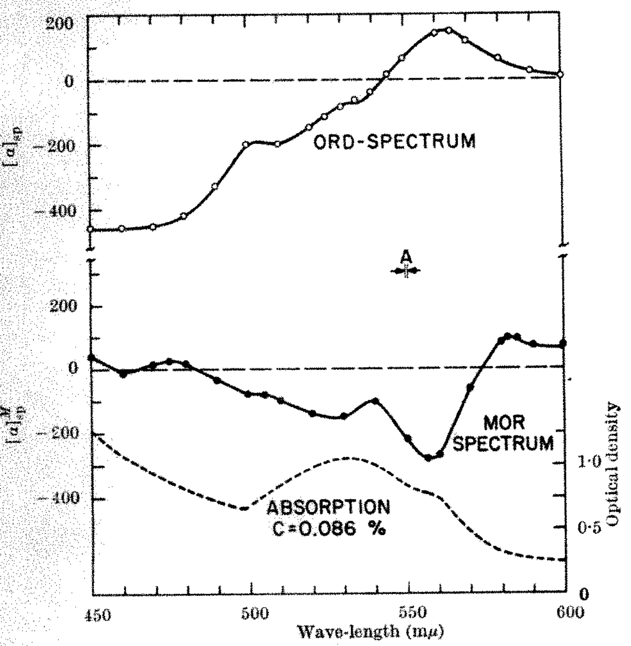

Fig. 3. MOR and ORD spectra of oxidized cytochrome *c* at 23° C in water. $[\alpha]_{sp}^{M}$, specific rotation; *A*, monochromator band pass

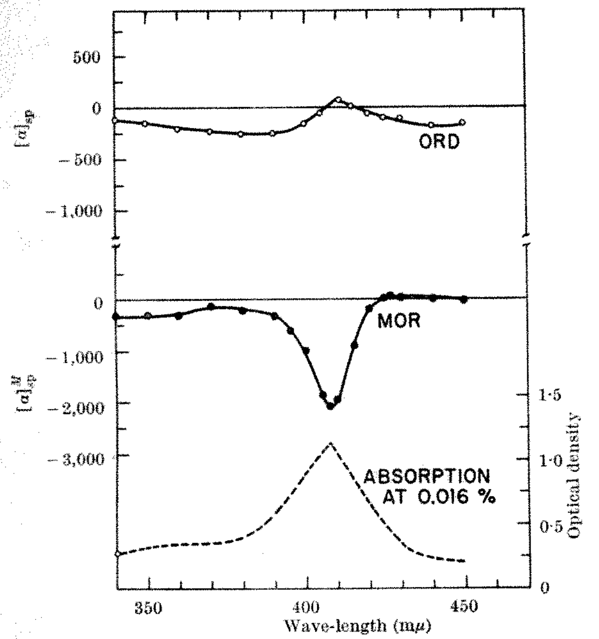

Fig. 4. MOR and ORD spectra of oxidized cytochrome *c* at the Soret band region at 23° C

where: θ is the angle of rotation in degrees; *l* is the path length in decimetres; *c* is the concentration in grams per ml.; and *H* is the magnetic field (gauss).

The apparatus and the techniques of measurement of the MOR spectra were the same as previously described[7].

Figs. 1 and 2 summarize the results for reduced cytochrome *c* at the absorption band regions corresponding to the α, β and γ (Soret) bands of the molecule. A comparison of the MOR spectrum with the optical rotatory dispersion (ORD) and the absorption spectrum at the α and β bands (549 and 520 mμ) clearly illustrates the greater fine structure of the MOR spectrum. The presence of six negative magnetic rotation peaks indicates that the two absorption bands of the molecule must be composite in structure and consist of at least six separate absorption peaks. The remarkable feature of the MOR spectrum is the large negative rotation peak at 549 mμ, with a specific magnetic rotation of − 1,450, at least 10 times as large as any other MOR peak of the spectrum. As shown in Fig. 3, this rotation is reduced to − 160 for the oxidized molecule, indicating the possibility of using the magnetic rotation to examine the kinetics of the reaction. Moreover, the fine structure of the MOR spectrum completely disappears when the molecule is oxidized to the ferric state.

Figs. 2 and 4 compare the measurements at the Soret band region of the molecule. Here a large negative rotation occurs in the MOR spectrum at the 410 mμ band with no distinctive changes on oxidation of the molecule. The natural optical activity measurements are also nonspecific in this respect. These results suggest that the more significant information about the electron transport function of cytochrome *c* is to be obtained from investigations at the long wave-length region of the spectrum, that is, at the α and β bands rather than γ (Soret) band. These observations indicate that the MOR spectral data may be quite useful for the investigation of the electron transport properties of cytochrome *c*.

Non-enzymatic Interactions of Reduced Coenzyme I with Inorganic Phosphate and Certain Other Anions

We previously reported[1] changes of the absorption spectrum of nicotinamide adenine dinucleotide (coenzyme I, abbreviated NAD^+) in solutions containing orthophosphate. In an extension of those investigations[2], it has been observed that dihydronicotinamide-adenine dinucleotide (reduced coenzyme I, abbreviated NADH) also reacts with orthophosphate, but in an entirely different manner. Similar changes were observed with dihydronicotinamide adenine dinucleotide phosphate (reduced coenzyme II, abbreviated NADPH) and certain other NADH-analogues. This is a preliminary report of our findings[3].

In spectrophotometric investigations, maximal changes were observed at 340 mμ and at 280 mμ. This is shown in the difference spectra of Fig. 1. It is apparent that the changes progress with time. Kinetic analysis[3,4] revealed that the decrease in absorbancy at 340 mμ fitted apparently first-order kinetics. However, the apparent first-order velocity constant was dependent on the concentration of the $H_2PO_4^-$ ion. In the *p*H range 6–8, a velocity constant independent of the phosphate concentration and the *p*H could be obtained by use of the second-order rate equation for the special case where one reactant is in great excess of the other, that is:

$$\frac{2\cdot 3}{b_0}\log\frac{a_0}{a} = kt \qquad (1)$$

In this equation, b_0 is the $H_2PO_4^-$ ion concentration (as obtained from the Hasselbach equation), and a_0 and a the absorbancies of NADH (equivalent to its concentration) at 340 mμ, at zero time and time *t*, respectively. At 34·4° C, the rate constant, *k*, was equal to $2\cdot 8 \times 10^{-4} \times M^{-1}$ sec^{-1}. Other polybasic anions with *pK′* values in the region between *p*H 6·0 and 8·0 were also reactive. This included $H_2AsO_4^-$ ($k = 4\cdot 9 \times 10^{-4}$); HSO_3^- ($k = 6\cdot 4 \times 10^{-4}$); and $H_2PO_3^-$ ($k = 3\cdot 0 \times 10^{-4}$). Monobasic (for example, Cl^-) or dibasic (for example, $SO_4^{=}$) anions fully dissociated at this *p*H range were almost non-reactive[3].

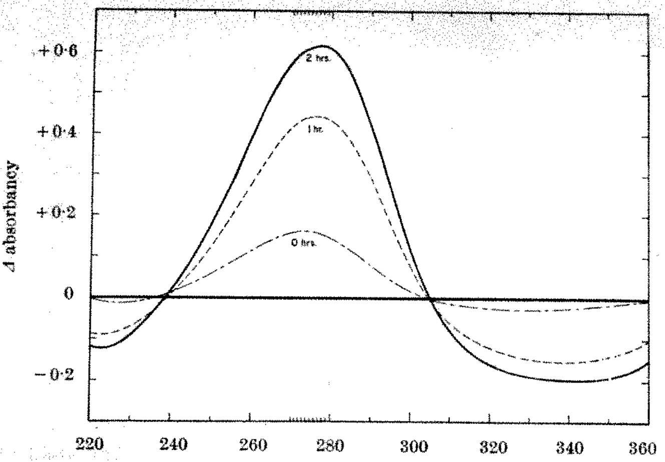

Fig. 1. Difference spectra of NADPH ($6{\cdot}17 \times 10^{-4}$ M) in 1·5 M potassium orthophosphate at *p*H 6·62 and 34·4° C, versus a reference solution containing NADPH in 0·05 M potassium orthophosphate. Solvent absorption was corrected for by the tandem-cell technique (ref. 12) and the sample in high concentration of phosphate was positioned in the sample beam of a Beckman *DK*-1 spectrophotometer. The light-path was 1 mm

Kinetic treatment of the changes at 280 mμ (Fig. 1) was also possible at a fixed *p*H and potassium orthophosphate concentration. After an initial and apparently instantaneous change in absorbancy (Fig. 1) which can be tentatively attributed to electrostatic interactions similar to those reported for NAD⁺ in high orthophosphate concentration[1,3], the subsequent time-dependent absorbancy changes could be described most simply by a reaction pathway involving two pseudo-first-order steps. Thus, the overall process can be written as follows:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad (2)$$

In this proposed mechanism, A is considered to be the species of NADH (still capable of oxidation by acetaldehyde-alcohol dehydrogenase), as it occurs at essentially zero time in 1·5 M potassium orthophosphate ($\varepsilon_{280} = 3{,}960$; $\varepsilon_{340} = 5{,}550$). The transformation from A to B was assumed to proceed at the same velocity that characterized the decrease in absorbancy at 340 mμ, that is, $k_1 = k$ of equation (1). The (phosphorylated ?) intermediate B ($\varepsilon_{280} = 18{,}250$) was further transformed (one or more steps?) to a final product C ($\varepsilon_{280} = 6{,}340$) at much slower speed. These interrelations are shown in Fig. 2.

From such considerations[4] it was demonstrated[3] that for the reaction of NADH in 1·5 M potassium phosphate at *p*H 6·62 and 34·4° C, $k_2/k_1 = 0{\cdot}07$. It, therefore, follows that a lag period (about 60 min., Fig. 2) should precede the appearance of a product C in measurable quantities. In other words, the intermediate B is reasonably stable under the conditions specified. It is hoped that determination of the second velocity constant in the presence of different anions and under various conditions of *p*H and anion concentration will contribute to the clarification of the nature of the decomposition of B.

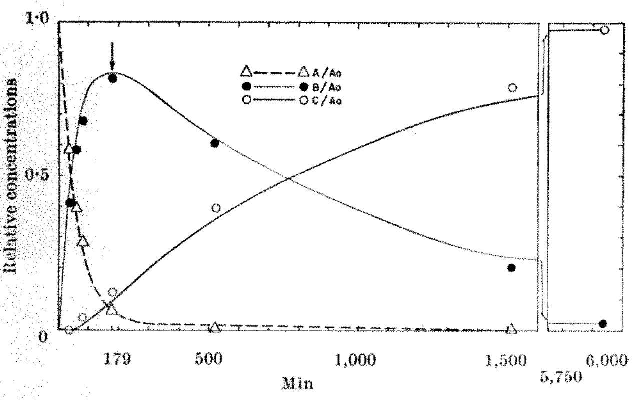

Fig. 2. Concentration-time curves for A, B, and C. Concentrations were computed from the molar extinction coefficient for each substance (see text) and from the relation $A + B + C = A_0$. (A_0 was the original quantity of NADH present in the medium.) The points assigned to its curve were calculated from equations for first-order reactions in series (ref. 4) and from the time of maximum accumulation of B (ref. 3) indicated in the figure by the arrow

A comparison of the rate constants for the reaction of various enzymatically reduced 3-substituted, 1,4-dihydropyridine derivatives in 1·5 M orthophosphate at *p*H 6·62 revealed that k_1 decreased over 300-fold in the order given here in the series: NADH; thiodihydronicotinamide–adenine dinucleotide; 3-acetyldihydro-pyridine–adenine dinucleotide and dihydropyridinealdehyde–adenine dinucleotide. Evidently the rate of reaction from A to B becomes slower with increasing effectiveness of the side-chain at position three of the dihydropyridine to act as an electron sink. The variation in k_1 with structure is thus in agreement with the changes of an overall velocity constant for the reaction of certain model compounds (for example, 1-benzyl-3-acetyl-1,4-dihydropyridine) in acid[5], and favours a reaction mechanism similar to that proposed by Anderson and Berkelhammer[5] involving β-protonation of 1,4-dihydropyridines, followed by reaction of the intermediate carbonium ion (at position 6) with a nucleophilic species (see also ref. 6). However, in contrast to the experimental conditions of Anderson and Berkelhammer, the hydrogen ion concentration in our experiments was extremely low (about $2{\cdot}4 \times 10^{-7}$ M) and the reaction rate apparently depended only on the anion concentration[3]. Furthermore, only polybasic anions with a second dissociation constant in the *p*H range between 6 and 8 were reactive. These considerations and a comparison of our findings with those of Wallenfels *et al.*[7] with model compounds in organic solvents have led us to the conclusion that the mechanism of the transformation from A to B involves a concerted action of the anion supplying a proton at the 5 position simultaneously with an attack of the resulting nucleophilic species at the 6 position of the 1,4-dihydropyridine (Fig. 3).

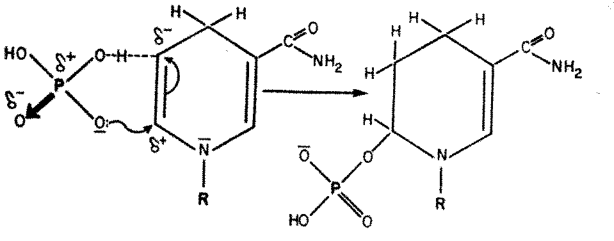

Fig. 3. Proposed mechanism of the spontaneous NADH–orthophosphate interaction at *p*H 6·62 (steps *A–B*)

It has also been demonstrated that 1,4-dihydronicotinamide ribonucleotide reacts more than twice as fast as NADH. This might be related to the folded state of NADH in solution[8]. The rate of reaction of the hypoxanthine analogue of NADH was the same as with NADH[3]. This would indicate that at *p*H 6·62 folding is independent of the presence of either a hydroxyl group or an amino group in the 6 position of the purine moiety.

It is probable that 'DPNH-*X*' of Chaykin, Meinhart and Krebs[9] may be identical or closely related to the product(s) described here. In their investigations, the chemical change of NADH in the presence of polybasic anions was catalysed by triose phosphate dehydrogenase, while in our experiments a reaction occurred spontaneously at relatively high anion concentrations. It is more difficult to evaluate the relation of the interactions and products described above to the phosphorylated NADH 'intermediate' of Griffiths[10]. The manner of decomposition of the latter[10] is reminiscent of the change between *B* and *C* as already described here, but more work is required to correlate these findings. In this connexion, it is interesting that in certain circumstances[11] the intramitochondrial concentration of orthophosphates might rise through an 'active transport' mechanism.

Infra-red Spectrophotometric Measurement of the Kinetics of the Action of β-Glucosidase

IN recent reports[1-3] it was shown that infra-red spectrophotometry could be applied to the measurement of the kinetics of enzymatic reactions. The purpose of this communication is to give data concerning the use of infra-red spectrophotometry to determine kinetics of a β-glucosidase reaction.

β-Glucosidase (emulsin) was purchased from Mann Research Laboratories, New York. The substrate, β-phenyl-D-glucoside, was prepared by the method of Montgomery *et al.*[4]. The system consisted of 0·5 ml. of enzyme solution added to 2·0 ml. of substrate solution, producing concentrations of 3·2 per cent β-phenyl-D-glucoside (w/v) and 0·2 per cent β-glucosidase (w/v) in *p*H 5·2 acetate buffer ($\mu = 0{\cdot}1$) at the beginning of the reaction, which was stirred magnetically.

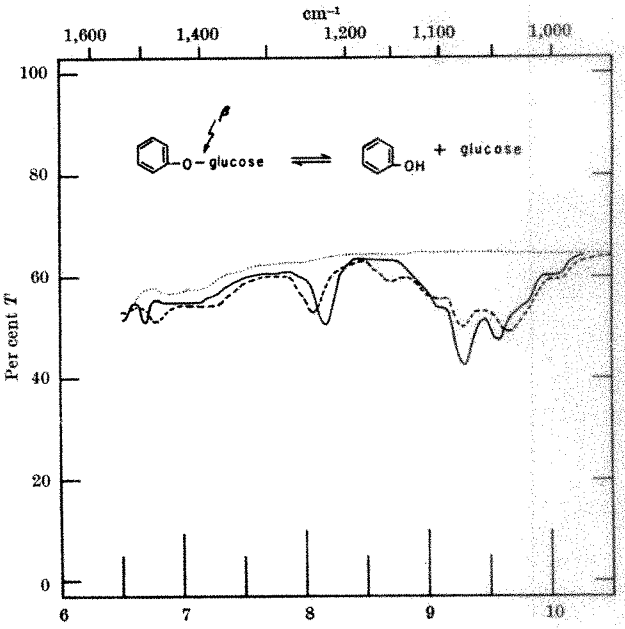

Fig. 1. The action of β-glucosidase on 3·2 per cent (w/v) β-phenyl-D-glucoside. · · · ·, water in an 'Irtran-2' cell, thickness 0·025 mm, versus water in the reference beam; ——, reaction mixture near beginning of the reaction (see text); – – – –, reaction mixture at end of enzymatic action (170 min)

Fig. 1 shows the course of action. The dotted line is the spectrum of water in an 'Irtran-2' cell of thickness 0·025 mm, measured against water in a reference 'Irtran-2' cell. The solid line is the spectrum of the enzymatic system near the beginning of the reaction, recorded against acetate buffer in the reference beam at a rate of 1μ per min. This curve was begun 2·5 min after the mixing of enzyme and substrate. The enzyme itself does not display a spectrum at 0·2 per cent concentration. As the reaction proceeds, several changes in the spectrum occur. The new band at 6·78μ is characteristic of free phenol in aqueous solution[5]. The band at 8·15μ (solid line), which is characteristic of the β-phenyl group linked to glucose through an oxygen atom, gradually disappears and becomes a band at 8·06μ (dashed line), characteristic of phenol[5] which is no longer bonded to glucose. As the reaction proceeds, a new band appears at 8·70μ, which does not exist in the spectrum of the original β-phenyl-D-glucoside. This band has been shown earlier[6] to be characteristic of the glucose molecule, and its intensity increases gradually as more free glucose appears. The spectrum of the final solution is identical with a solution made up of stoichiometric amounts of phenol and glucose, assuming complete hydrolysis.

The 'Irtran-2' (ZnS) does not interfere with the assay of the enzymatic reaction, since it was demonstrated that spectral changes were the same whether they were determined on aliquots removed from the reaction mixture at various time intervals, or were determined directly on the reaction mixture contained in the cell. First-order kinetics were calculated from absorbance data of the band at 8·70μ from the equation:

$$k = \frac{1}{t} \log \frac{A_0 - A_\infty}{A_t - A_\infty}$$

In a typical run A_∞, the absorbance of the band at the end of the reaction, was 0·2864; A_0, the initial absorbance of the band (extrapolated to time 0), was 0·2528; and A_t was the absorbance of the band at time t, varying from 0·2557 to 0·2857. Some typical examples of k were 0·0106, 0·0096, 0·0134 and 0·0112, with an average k of 0·0112 min⁻¹.

The methods reported here should be useful in the application of infra-red spectrophotometry in other enzymatic reactions and other chemical reactions occurring in water.

Inhibitory Levels of Fluoride on Mammalian Cells

As a preliminary to more detailed investigations of the cellular effects of fluorides, growth inhibitory levels have been determined on mammalian cells. Because of the widespread concern about possible toxic effects of fluoride when used for water fluoridation, these levels are of more than theoretical interest.

Murine leukæmic lymphoblasts, *L5178Y* strain, were cultured following the method of Fischer[1], at 37° C, in 16 mm × 125 mm closed culture tubes, containing serial dilutions of sodium fluoride. Below a concentration of 5×10^5 cells/ml. these cells reproduce logarithmically approximately every 12 h. Each tube contained 5 ml. of culture medium with approximately 2,000 cells/ml. At the end of four days cell population was determined using a Coulter counter. This was readily accomplished since the cells grow freely in the medium without attaching to glass. The number of cell generations that have occurred was plotted as a function of the logarithm of the concentration of fluoride in the medium. By extrapolation the molarity of fluoride was determined which would result in a 20 per cent or a 50 per cent reduction in cell generation production (*Gd* 20 and *Gd* 50).

Significant inhibition has not been found at a concentration of 3×10^{-4} M F^- (5–6 p.p.m. F^-), and might possibly have been detected at $4{\cdot}4 \times 10^{-4}$ M F^- (8–9 p.p.m. F^-). Growth depression was rapid from $5{\cdot}9 \times 10^{-4}$ M F^-, and was linear above a concentration of 10^{-3} M F^- (19 p.p.m.) (Fig. 1). The amount of fluoride presumably required to inhibit the rate of cell reproduction by 20 per cent (*Gd* 20) was $1{\cdot}1 \times 10^{-3}$ M F^- (20 p.p.m.) (range 1·04–1·13) and by 50 per cent (*Gd* 50) was $1{\cdot}5 \times 10^{-3}$ M F^- (30 p.p.m.) (range 1·38–2·04). It is apparent that much higher concentrations of fluoride were required to demonstrate growth inhibition in these mammalian cells than the $5{\cdot}5 \times 10^{-5}$ MF^- (1–1·2 p.p.m. F^-) usually advocated for water fluoridation.

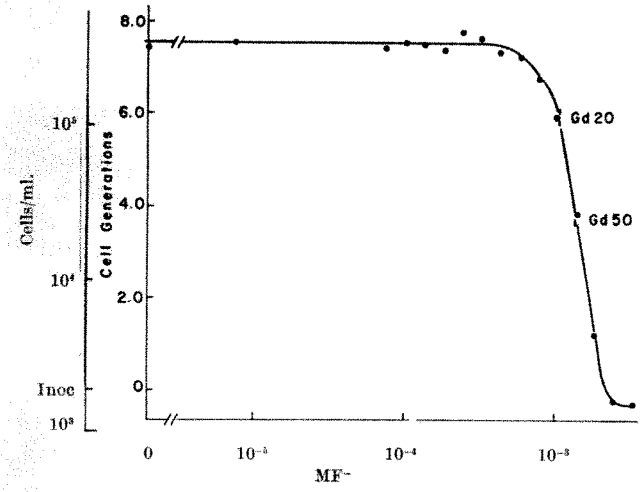

Fig. 1

These results differ from those reported by Berry[2], who interpreted his data to indicate an effect on mammalian cells (strain *L* mouse fibroblasts and HeLa S–3_{oxf} cells) with a fluoride level of 0·1 p.p.m. ($5{\cdot}3 \times 10^{-6}$ M F^-).

Although the anti-caries effect resulting from the recommended 1–1·2 p.p.m. F^- ($5{\cdot}3$–$6{\cdot}3 \times 10^{-5}$ M F^-) in the water supply may very well be due to a local effect on the teeth[3], the changes which occur in chronic fluorosis, such as mottling of the teeth and skeletal effects, are probably secondary to cellular dysfunction caused by toxic levels of fluoride in the immediate environment of the affected cell. This interference of cell function may be related to inhibitory effects of fluoride on specific enzyme systems, some of which are known to be affected by levels of fluoride which were found to inhibit the cells in the work recorded here[4,5].

Water levels of fluoride differ from blood or tissue levels. Blood levels of fluoride tend to be considerably lower than water levels and bone levels tend to be considerably higher[6,7]. Most of the fluoride in bone, however, appears to be bound with calcium as fluoroapatite and may not be physiologically active. Even so, it seems reasonable to assume that the effect on bones and teeth is related to the high concentration of fluoride in these structures and that pathological abnormalities occur when the level of ionized fluoride (which differs from total fluoride) rises above a critical level (affecting cell function). The kidney, which excretes fluoride, and therefore contains higher levels than other soft tissues, is the organ affected when the water-level is increased (approximately 125 p.p.m. in the water supply is required to cause pathological changes). This would indicate that, above a critical level of fluoride, cell function may be affected in the kidney as well as in bone[8].

Other soft tissues do not demonstrate pathological changes except with an intake of excessive amounts of fluoride, and levels of fluoride in these tissues are below those required to affect the reproduction of the cells used in this work[9].

An effect on any tissue, therefore, may depend on a sufficient level of fluoride in that tissue to affect cell function, although the critical level of fluoride necessary to produce an adverse effect may or may not differ in different tissues. This toxicity study is in agreement with those findings which indicate that 1–1·2 p.p.m. fluoride in the drinking water will produce no adverse effects.

Transfer of Melanin Granules from Melanocytes to the Cortical Cells of Human Hair

THE manner by which the cortical cells of developing hair fibres acquire melanin pigment has been the subject of much speculation. Some authors have postulated that the pigment granules are actively inoculated into the prekeratinized cells by way of the dendritic processes of the melanocyte (cytocrine activity)[1,2], whereas others have suggested that pigment granule transfer involves the active ingestion (phagocytosis) of the granules by the cortical cells[3,4]. Birbeck and Mercer[3,4], who have found some evidence for this latter process, observed small 'pseudopods' enveloping the pigmented processes of black hair melanocytes at a point adjacent to the developing cortical cells of hair.

If the phagocytosis of pigment granules does indeed occur, then remnants of cell membranes ought to be apparent in the vicinity of the pigment granules in the cortex of mature hairs. That there is a close association

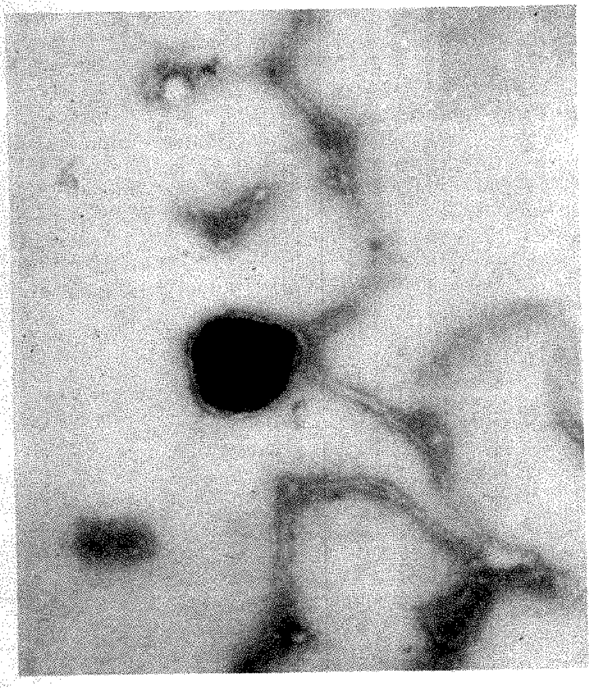

Fig. 1. Electron micrograph of a transverse section of human hair

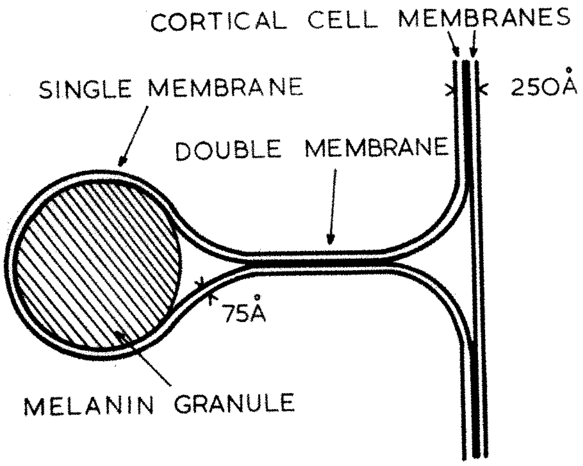

Fig. 2. Schematic diagram illustrating the association between melanin granules and the cortical cell membranes of hair

between pigment granules and the cortical cell membranes of hair has already been demonstrated in electron micrographs of transverse sections of osmium-stained hair[5]. This latter work, however, failed to reveal cell membranes around the pigment granules themselves. The reason for this is now thought to be that, because osmium tetroxide reacts so vigorously with melanin, the periphery of the pigment granules is obscured from view in the electron microscope. To overcome this shortcoming in technique, a method for staining thin sections of hair, which reveals the cell membranes in the cortex of hair without obliterating any of the detail adjacent to the pigment granules, was used in the present work.

Untreated human hair was dehydrated in ethanol and embedded in a prepolymerized mixture of methyl and *n*-butyl methacrylate (1 : 1 v/v) in the normal manner. Thin transverse sections of the embedded fibres were obtained with a Porter Blum ultramicrotome and collected on collodion-covered gold electron microscope grids. The specimen grids were then immersed in a centrifuged 10 per cent solution of dodeca tungstophosphoric acid in 50 per cent ethanol for 1 h and then washed in fresh 50 per cent ethanol for a further hour.

Using the staining technique already described here, the cell membranes and nuclear material in electron micrographs of the hair cortex were very well defined. Single granules and groups of two or three granules were seen to be intimately associated with adjacent cortical cell membranes. In a few cases the pigment granules were connected by a long finger of double membrane to the cortical cell membrane, and frequently single granules or groups of granules were enclosed by a single unit membrane (Fig. 1) similar in structure to that of the cell membrane. The reason why not all the pigment granules were apparently connected to a nearby cortical cell membrane is thought to be that some of the connecting membranes were either above or below the plane in which the sections were cut. A schematic diagram illustrating the observed association between pigment granules and cortical cell membranes is given in Fig. 2.

It is considered that this close association between the pigment granules and the cell membranes in mature hairs is a consequence of phagocytosis. It is envisaged that melanin granules exude from the ends of melanocyte dendrites into the space between pre-keratinized cortical cells of the hair follicle, where they are ingested singly or in groups by the cortical cells by phagocytosis. The ingestion of the pigment-laden tips of melanocytic dendrites in this manner would also explain the regular end-to-end arrangement of pigment granules, which is frequently encountered in electron micrographs of longitudinal sections of hair.

Synthesis of Cystathionine and its Control in *Salmonella typhimurium*

CYSTATHIONINE formation in *Escherichia coli* involves the functioning of two enzymes[1-3]. The first enzyme is present in certain cystathionine-requiring auxotrophs such as *E. coli* strain 7/9 but absent from others (such as strain 2/2) and catalyses the formation of *O*-succinyl homoserine from homoserine and succinyl coenzyme *A*. The nature of the product was originally deduced from the chemical and biological properties of the compound[3] and this was confirmed by comparison with chemically synthesized *O*-succinyl homoserine[4]. The second enzyme which is absent from strain 7/9 but present in strain 2/2 forms cystathionine from *O*-succinyl homoserine plus cysteine[2]. Further evidence for the functioning of *O*-succinyl homoserine as a methionine precursor in *E. coli* was afforded by the observation[5] that strain 7/9 accumulated *O*-succinyl homoserine when grown with limiting amounts of homocysteine although the addition of methionine abolished the accumulation. Nutritional and genetic investigations with methionine-requiring strains of *Salmonella typhimurium*[6] suggested that the biosynthetic pathway might be the same as in *E. coli*. Two other observations support this view. First, organisms of *S. typhimurium* strain *B*23, a cystathionine-requiring mutant, accumulate *O*-succinyl homoserine in the culture fluid[5], while a genetically dissimilar cystathionine-requiring strain (strain *A*15) shows no accumulation. Secondly, extracts from *S. typhimurium* strain *A* form cystathionine from *O*-succinyl homoserine plus cysteine[7]. These data supported the view that cystathionine and *O*-succinyl homoserine are methionine precursors in *S. typhimurium* and, as the accumulation of *O*-succinyl homoserine by strain *B*23 (like that with *E. coli* strain 7/9) was prevented by methionine[5], it appeared that control of the biosynthetic pathway might be similar to that in *E. coli*[2]. The present work shows that *S. typhimurium* contains both enzymes of cystathionine formation and that enzymatic repression and feed-back inhibition occur.

Ultrasonic extracts of *S. typhimurium* strain *B*23 grown with limiting amounts of homocysteine catalysed the synthesis of *O*-succinyl homoserine from homoserine and succinate; the activity was assayed by the uptake of ^{14}C-succinate into *O*-succinyl homoserine as described by Rowbury and Woods[4]. The amount of enzyme present in strain *B*23 was much less than that in *E. coli* strain 7/9, but, as strain 7/9 accumulates 20 times as much *O*-succinyl homoserine as strain *B*23[5], this was not unexpected. Homoserine *O*-trans-succinylase of strain *B*23 was subject to enzymatic repression as growth with methionine (1·5 mM) reduced the enzyme level to 20 per cent. Methionine also inhibited the activity of the enzyme in extracts from organisms grown without methionine. Activity was reduced to 50 per cent by 1 mM DL-methionine and to 20 per cent by 5 mM methionine (Table 1). The formation of *O*-succinyl homoserine by intact organisms of strain *B*23 is also subject to feed-back inhibition by methionine, and the enzyme *in vivo* is much more sensitive to methionine. Thus accumulation was reduced to 6 per cent by 0·2 mM DL-methionine (Table 1). Homoserine *O*-trans-succinylase of whole organisms is also much more susceptible to inhibition by methionine than the cell-free enzyme in *E. coli* strain 7/9 (ref. 8).

Table 1. FEED-BACK INHIBITION OF HOMOSERINE *O*-TRANS-SUCCINYLASE BY METHIONINE IN *Salmonella typhimurium* STRAIN *B*23

DL-Methionine (mM) added to the reaction mixture	Homoserine *O*-trans-succinylase of intact organisms	Homoserine *O*-trans-succinylase of ultrasonic extracts
0	100	100
0·2	5·8	—
0·5	—	60
1	3·0	49
5	1·0	20

Values are given as percentages of the control (without methionine).

Extracts from *S. typhimurium* strain *A*15 formed cystathionine from *O*-succinyl homoserine plus cysteine, and in this case the level of enzyme activity was similar to that in *E. coli* strain 2/2 (Table 2). Activity was absent from *S. typhimurium* strain *B*23, and in strain *A*15 was greatly reduced by the omission of cysteine. This enzyme was also subject to repression by methionine; growth with 1·5 mM DL-methionine reduced activity to 22 per cent in extracts from strain *A*15 (Table 2). From these data it appears that *S. typhimurium* strain *B*23 resembles *E. coli* strain 7/9 while *S. typhimurium* strain *A*15 is like *E. coli* strain 2/2.

Table 2. ENZYMATIC REPRESSION OF CYSTATHIONINE SYNTHETASE OF *Salmonella typhimurium* STRAIN *A*15

	Cystathionine formed from *O*-succinyl homoserine (μmmole/mg protein/h)			
	Strain *A*15		Strain 2/2	
	Cysteine present	Cysteine absent	Cysteine present	Cysteine absent
Organisms grown without methionine	165	12·5	160	15
Organisms grown with methionine (1·5 mM)	36	12·0	30	12

S. typhimurium strains *A*15 and *B*23 also show homocysteine methylase activity, and in each strain formation of the enzyme was repressed by growth with methionine. Growth with 1·5 mM DL-methionine reduced enzyme synthesis to 15 per cent in strain *B*23 and to 25 per cent in strain *A*15. *S. typhimurium* has cystathionase activity also, but this activity in strain *B*23 is not appreciably reduced by growth with methionine.

Thus methionine synthesis in *S. typhimurium* appears to be like that in *E. coli* and to involve the intermediate formation of *O*-succinyl homoserine, cystathionine and homocysteine. The two cystathionine-forming enzymes and the homocysteine methylase complex are subject to enzymatic repression by methionine in *S. typhimurium*, and the first enzyme of the pathway (homoserine *O*-trans-succinylase) is also regulated by feed-back inhibition of its activity by methionine.

PHYSIOLOGY

Effect of Thiocyanate on Secretion of Acid and Uptake of Oxygen by Gastric Mucosa of the Frog

THE ratio of acid secretion by gastric mucosa to the oxygen uptake involved in the secretory process does not seem to have a value significantly greater than four[3,4] as predicted by the redox theory of acid secretion[2,6]. Forte and Davies[5] have recently reported a series of experiments on electrically short-circuited gastric mucosæ of the bullfrog, in which thiocyanate produced a decrease in oxygen uptake and acid secretion. The ratio $\Delta q\text{H}^+/\Delta q\text{O}_2$ ($q\text{H}^+$ = rate of acid secretion, $q\text{O}_2$ = rate of oxygen uptake in the same units) was calculated from the mean rates of acid secretion and oxygen uptake before and after thiocyanate in each experiment. This ratio had high mean values which varied inversely with the concentration of thiocyanate from 5·1 to 12·0.

This finding was not confirmed in the experiments described here, which show that thiocyanate lowers the value of the stoichiometry between acid secretion and oxygen uptake. An everted sac technique was used[1]. Everted sacs of gastric mucosa obtained from starved frogs were prepared and filled with a medium of the following composition: 112·2 mM sodium chloride, 4·5 mM potassium chloride, 1·1 mM calcium chloride, 0·6 mM magnesium sulphate, 0·7 mM sodium phosphate buffer (*p*H 7·4), 11 mM glucose. The sacs were incubated initially in the same medium. Uptake of oxygen was measured manometrically at 25° C (direct method of Warburg; gas phase air), and acid secretion was measured by renewal of the incubating medium at intervals of 45 min and electrometric titration of the medium back to its initial *p*H. Twelve experiments were performed. Each sac was first incubated 5–7 times in the glucose–saline, and afterwards 3–4 times in the same saline containing 6 or 12 mM sodium thiocyanate. Acid secretion occurred spontaneously in all experiments.

The observations made were pooled and acid secretion before and after the addition of thiocyanate to the incubating medium was plotted as a function of oxygen uptake. The regression of acid secretion on oxygen uptake appeared to be linear both before and after thiocyanate. The following linear equations were obtained by the method of least squares:

before thiocyanate

$$q\text{H}^+ = 2{\cdot}59\ (q\text{O}_2 - 0{\cdot}029)\ \mu\text{M/mg dry wt./h} \qquad (1)$$
$$(n = 67,\ r = 0{\cdot}7)$$

after thiocyanate

$$qH^+ = 0{\cdot}89\,(qO_2 - 0{\cdot}029)\ \mu\text{M/mg dry wt./h} \qquad (2)$$
$$(n = 45,\ r = 0{\cdot}6)$$

The coefficients of correlation are not high but both are significant ($P < 0{\cdot}001$). There is also a significant difference between the regression coefficients ($P < 0{\cdot}001$). The variance of the coefficient of regression before thiocyanate indicates a range (mean ± 3 *S.D.*) of 1·69–3·49 for this parameter. These figures compare with the 99 per cent confidence limits obtained by Davenport[3], namely, 0·95 and 3·71.

The coefficient of regression of acid secretion on oxygen uptake gives the ratio of acid secretion to the associated oxygen uptake, as may be seen from the regression equations given here. It would appear that this ratio does not have values exceeding four with a high degree of probability, and that thiocyanate reduces its value.

The following mean rates of acid secretion and oxygen uptake were observed before and after thiocyanate in the present experiments.

	$\overline{qH^+}$ (μM/mg dry wt./h)	$\overline{qO_2}$ (μM/mg dry wt./h)
(1) Before thiocyanate	0·102	0·069
(2) After thiocyanate	0·022	0·053

Thiocyanate produced a 78 per cent decrease in the mean rate of acid secretion, but only a 23 per cent decrease in the mean rate of oxygen uptake. The oxygen uptake associated with the acid secretion abolished by thiocyanate would seem to remain largely unaffected by this agent. For this reason Forte and Davies[5] could have obtained high values for the ratio $\Delta qH^+/\Delta qO_2$.

I thank Mr. J. R. P. O'Brien for his advice.

Radiation Inactivation of the Immunological and Biological Activities of Human Chorionic Gonadotropin

RADIATION of protein hormones or enzymes results in loss of activity. The rate of inactivation can be used to estimate the volume and weight of the active portion of the molecule if this rate is exponentially related to the dose of ionizing radiation and low-density ionizing radiation is used[1]. Previous investigations[2] have demonstrated that the rate of loss of hormonal activity of human chorionic gonadotropin (HCG) exposed to a 2·0-MeV electron beam was exponential and was identical when measured by four bioassays: in intact immature rats by (1) uterine weight, and (2) ovarian hyperæmia responses; in hypophysectomized rats by (3) testes, and (4) prostate weight responses.

Since hormonal and immunological activities of HCG may vary independently in certain circumstances[3], we have undertaken to compare the rate of radiation inactivation of HCG measured by immunoassay as compared to bioassay.

Detailed methods of preparation and radiation of HCG and of radiation dosimetry will be reported in a separate publication[2]. In brief, 2,000–5,000 I.U. of HCG were placed on stainless-steel planchets, lyophilized and exposed to a 2·0-MeV electron beam for varying lengths of time. The radiated hormone was bioassayed by means of the prostate and testes weight responses in immature hypophysectomized male rats[4,5] and loss of activity calculated as reported[2]. 250–500 animals were used to assay each radiation batch of HCG. Antisera to a Freund's adjuvant emulsion of a partially purified (7,000 I.U./mg) preparation of HCG were made in New Zealand white rabbits, such that 1 ml. of antiserum was capable of neutralizing the biological activity of 1,000–4,000 I.U. of HCG as measured by the prostate weight response of the hypophysectomized rat. A single line was observed when the antisera were analysed by double diffusion in agar against HCG. Immunological assays of HCG were performed by two methods: (1) by hæmagglutination inhibition as modified by Wide[5] from the technique of Boyden[6] utilizing HCG-sensitized, tanned, formalinized sheep red blood cells; (2) by a modification of the radioimmunoassay described by Feinberg[7] and by Skom and Talmage[8] utilizing an HCG preparation of 12,000 I.U./mg for radioiodination. In the latter assay, the presence of hormone is detected by its competition with radioiodinated hormone for reaction with rabbit antibody. The immune complex is afterwards precipitated with sheep anti-rabbit γ-globulin. Supernatant radioactivity is an index of amount of hormone. In order to eliminate the possibility that non-hormonal urinary contaminants were being measured by the immunoassays, standard amounts of HCG were prepared in an extract of the urine of a hypophysectomized human and in phosphate buffered saline. Results of simultaneous assays of both preparations in both immunoassay systems were essentially identical.

Multiple assays were performed at each radiation dosage and biological results were verified on eight separately radiated batches of hormone. In ten assays on two separately radiated batches of hormone, loss of immunological and hormonal activity was measured on the same preparations.

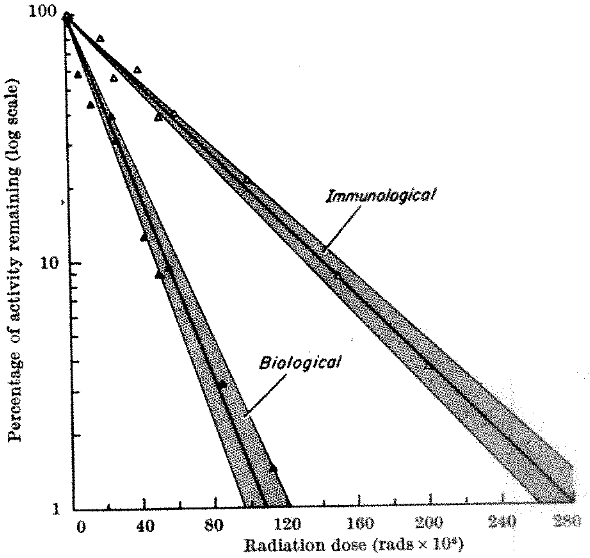

Fig. 1. The rates of inactivation are represented by regression lines; shaded areas represent 95 per cent confidence limits of the regression line. ▲, ventral prostate assay; △, hæmagglutination inhibition assay

Results are summarized in Table 1 and Fig. 1. Fig. 1 demonstrates a linear relationship between the logarithm of percentage of activity remaining and the radiation dosage obtained for both immunological and biological data. This indicates that in both instances a population of uniform-sized active units is being measured; significant heterogeneity in the size of active units would result in departure from linearity[1].

The rate of inactivation was consistently greater when assayed biologically than when measured immunologically.

Table 1. RADIATION INACTIVATION OF IMMUNOLOGICAL AND BIOLOGICAL ACTIVITIES OF HCG

Assay	D_{37} × 10^{-6} rads (95% limits)	Target volume-mμ³ (95% limits)	Mol. wt. × 10^{-3} (95% limits)
Biological			
Prostate weight	25·67 (23·10—28·91)	32·46 (28·57—36·36)	26·9 (23·7—30·1)
Testes weight	25·63 (23·12—28·76)	32·54 (28·74—36·35)	27·0 (23·8—30·1)
Immunological			
Hæmagglutination inhibition	63·01 (58·90—67·73)	12·90 (11·95—13·87)	10·7 (9·9—11·5)
Radioimmunoassay	58·31 (50·63—68·74)	14·01 (11·76—16·28)	11·6 (9·8—13·5)

The radiation dose required to reduce activity to 36·8 per cent (D_{37}) as measured biologically by prostate weight response was 25·67 × 10^6 rads ($\pm$ 1·29 × 10^6 (*S.E.M.*)) and as measured by testes weight response was 25·63 × 10^6 rads ($\pm$ 1·26 × 10^6). The D_{37} measured by hæmagglutination inhibition was 63·01 × 10^6 rads ($\pm$ 2·09 × 10^6) and by radioimmunoassay was 58·31 × 10^6 rads ($\pm$ 4·27 × 10^6). The target volume calculated[1] from biological data averaged 32·5 mμ³. The target volume calculated from immunological data averaged 13·5 mμ³. Assuming a density of 1·376 g/c.c. the molecular weight calculated from biological data was 27·0 × 10^3, which agrees well with previous physical measurements[9]. The molecular weight calculated from immunological data was 11·2 × 10^3.

These findings are interpreted as demonstrating that the structural unit required for immunological activity of HCG is considerably smaller than the unit required for biological activity.

Origin of Neuraminic Acid in Human Seminal Fluid

THE occurrence and possible function of the neuraminic acids in mammalian tissues and fluids is a matter of great interest. Large amounts of *N*-acetylneuraminic acid have been demonstrated in the seminal fluid of man[1,2], bull[3] and boar[4]. Analysis of the secretions of the accessory genital organs of the boar showed that the mucin from the bulbourethral glands contained 4–4·5 per cent (fresh weight) of neuraminic acid. The concentration was less in the seminal vesicles and negligible in the other glandular secretions[5]. In man the average concentration of neuraminic acid was in the seminal vesicle fluids 231·9 mg/100 ml., in the prostatic secretions 60·6 mg/100 ml., and in the seminal fluid 124·2 mg/100 ml. From these data, Warren[2] calculated that approximately two-thirds of the seminal fluid came from the prostate gland. It is, however, difficult to calculate the relative contribution of the various glandular systems to the ejaculate by using data obtained from extracts of autopsy material.

It is known that during ejaculation the three main glandular systems contributing to the ejaculate are discharged successively. The first portion comes from the prostate gland, the second from the testes and epididymis, and the third from the seminal vesicles. During ejaculation the secretions from these three glandular systems become more or less mixed. By estimating the concentration of acid phosphates (from the prostate gland), spermatozoa (from the testes, epididymis and vas deferens) and fructose (from the seminal vesicles) in each portion of a 'split-ejaculate' it is possible to calculate the amount secreted by each of these glandular systems[6].

In the present investigation the origin of neuraminic acid was examined by analysing each portion of split-ejaculates for its content of acid phosphatase, fructose and neuraminic acid. The procedure and analytical methods have been described earlier[6,7]. Neuraminic acid was determined by the thiobarbituric acid method[3]. The various seminal fractions were not examined for their content of spermatozoa since the secretions of the testes, epididymis and ductus deferens are relatively small and probably add little to the neuraminic acid content of the semen[2,6]. Analysis of the sperm cells by the Ehrlich or resorcinol test showed the presence of only very small amounts of neuraminic acid[2]. Seminal fluid was received from five healthy male volunteers aged 25–30.

The analytical data from a typical experiment is presented in Fig. 1. The results indicate that neuraminic acid is secreted in nearly equal amounts from both the prostate gland and the seminal vesicles. This secretory pattern is not usual since most substances investigated are secreted mainly or entirely from a single gland.

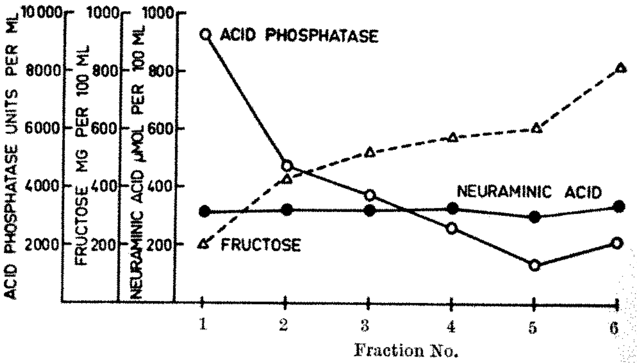

Fig. 1. Concentration of acid phosphatase, fructose and neuraminic acid in different portions of human seminal fluid collected with the 'split-ejaculation method'

The highest concentration found in the seminal vesicle secretions (last fractions) was 430 μmoles/100 ml. This is lower than the mean value (750 μmoles/100 ml.) given by Warren[2] for the seminal vesicle fluid obtained at autopsy. Moreover, the mean value given by Warren[2] for the prostatic fluid (196 μmoles/100 ml.) is below the concentrations found in the first fractions of the ejaculates (250–350 μmoles/100 ml.).

The concentration of neuraminic acid in the total ejaculates varied between 200 and 350 μmoles/100 ml. This is in the same order of magnitude as found by Svennerholm[1] and Warren[2].

The significance of neuraminic acid for human fertility is not known, but work on this problem is in progress.

This work was supported by the Swedish Medical Research Council and the Population Council, New York. Crystalline *N*-acetylneuraminic acid was kindly supplied by Dr. L. Svennerholm, Gothenburg.

PHARMACOLOGY

Neural and Photic Regulation of 5-Hydroxytryptophan Decarboxylase in the Rat Pineal Gland

THE mammalian pineal gland has high concentrations of serotonin[1-3] and of 5-hydroxytryptophan decarboxylase (5-HTPD) (ref. 4), the enzyme which synthesizes serotonin. Innervation of the rat pineal gland is derived largely or solely from sympathetic nerve fibres the cell bodies of which are located in the superior cervical ganglia[5]. Fluorescent microscopic findings indicate that a large part of pineal serotonin content is localized in sympathetic nerve endings[2]. Following superior cervical ganglionectomy, the specific indole fluorescence in these nerves disappears[2] and there is a 50 per cent decrease in pineal serotonin[2,3].

When rats are placed in constant light, there is a considerable reduction in both pineal weight[6] and in the activity of the enzyme in the pineal gland which makes melatonin[7]. These effects of constant light can be eliminated by bilateral orbital enucleation or by bilateral superior cervical ganglionectomy[8]. It has been shown that the serotonin content of pineal glands of rats in constant light for six weeks is one-half that of rats under diurnal lighting conditions[1]. On the other hand, an increase in pineal serotonin content was observed during the light phase of diurnal illumination[9].

We have recently developed a sensitive assay for the estimation of 5-HTPD activity which enabled us to measure the 5-HTPD activity of individual rat pineal glands[4]. Investigations were carried out to determine if the serotonin-synthesizing capacity of the rat pineal gland, as measured by its 5-HTPD activity, was subject to photic regulation. Our experiments indicate that exposure of rats to constant light results in a marked increase in pineal 5-HTPD activity as compared to rats kept in constant darkness. In addition, the effects of constant light on 5-HTPD activity can be eliminated by blinding, by interrupting the sympathetic innervation of the pineal gland, or by treatment with bretylium, a drug which blocks sympathetic nerve impulses[10].

Groups of 10–20 Sprague–Dawley female rats weighing 160–180 g were placed in constant light or in constant darkness (except for a 25-W red light bulb which was used while the cages were cleaned) in rooms equipped with double door light baffles and air conditioning. Animals were killed while still in the light or dark rooms. Control animals in constant light or darkness were killed at the same time as drug treated or operated animals, between 9 and 10 a.m. Pineal glands were quickly removed, weighed, and homogenized in 1 ml. of 0·05 M phosphate buffer, *p*H 7·4. 5-HTPD (ref. 4) and monoamine oxidase[11] activities were assayed by procedures previously described. None of the experimental treatments altered body-weight.

Rats kept in constant light for six days had almost twice as much pineal 5-HTPD activity as litter-mates placed in constant darkness for the same time-period (Table 1). The difference in enzyme activity was significant whether computed per pineal or per unit weight. Pineals of rats in constant light weighed less than those of animals in constant darkness, but the difference was not statistically significant. Since, in other experiments from this laboratory using large numbers of rats[7], light exposure for 6 days produced statistically significant decreases in pineal weight, the failure to obtain significant alterations in pineal weight in this experiment may have been due to the small number of animals used.

It has been shown that the regulation by light of pineal melatonin-synthesizing capacity is mediated by the retina and the superior cervical ganglia[8]. In order to ascertain whether light influences pineal 5-HTPD via the same pathway, animals were subjected to bilateral orbital enucleation or bilateral superior cervical ganglionectomy. One day after the operations, the rats were placed in continuous light or darkness for 30 days along with control animals. The eyelids of the ganglionectomized rats were removed to correct for possible effects of ptosis.

Table 1. EFFECT OF CONSTANT LIGHT OR DARKNESS FOR SIX DAYS ON RAT PINEAL 5-HTPD

Group	No.	Pineal weight (mg)	mμM ^{14}C-serotonin formed/h/pineal	mμM ^{14}C-serotonin formed/h/mg
Dark	7	1·14 ± 0·31	12·5 ± 0·9	11·7 ± 1·5
Light	6	0·99 ± 0·10	17·7 ± 2·1*	18·1 ± 2·3*

* Differs from dark value $P < 0·05$.

5-HTPD activity was determined as described (ref. 4) by incubation of pineal tissue with 5-hydroxytryptophan-^{14}C and measuring the ^{14}C-serotonin formed.

Control animals placed in constant light for 30 days had significantly smaller pineal glands ($P < 0·01$) with almost twice the 5-HTPD activity of their litter-mates in constant darkness (Fig. 1). The increase in 5-HTPD was statistically significant whether expressed per unit weight ($P < 0·001$) or per whole pineal gland ($P < 0·01$). In confirmation of previous findings[7], light produced no difference in the activity of monoamine oxidase, an enzyme presumably involved in the metabolism of serotonin. Blinding or removal of the superior cervical ganglia eliminated the difference in pineal weight between light and dark exposed groups, confirming earlier findings[8], and blocked the enhancement by light of pineal 5-HTPD activity. These observations indicate that the path whereby light affects pineal 5-HTPD activity involves the retina and the sympathetic nervous system.

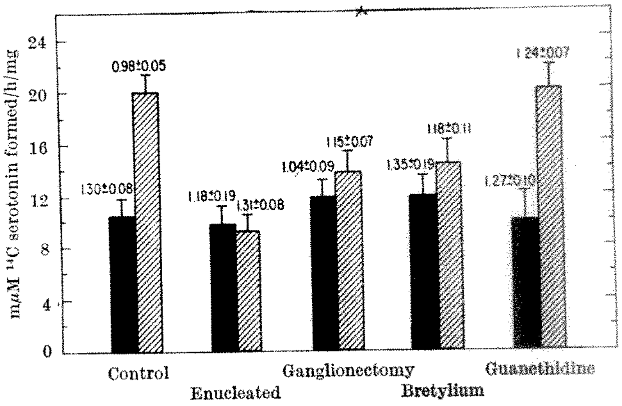

Fig. 1. The effect of bilateral orbital enucleation, superior cervical ganglionectomy, or treatment with bretylium or guanethidine on the response of rat pineal weight and 5-HTPD activity to constant light or darkness. The vertical bars represent the standard error of the mean (*S.E.M.*). The numbers over the bars show pineal weight (mg ± *S.E.M.*). Black, constant dark; hatched, constant light

Other groups of rats were placed in continuous light or dark environments two days after beginning the daily intraperitoneal injections of bretylium (20 mg/kg) or guanethidine (20 mg/kg). Daily drug treatment was continued for 30 days in the light and darkness. Bretylium and guanethidine are known to block sympathetic nerve impulses[10,12]. Guanethidine, in addition, depletes a number of tissues of norepinephrine[13,14] and serotonin[15,16]. If the effect of light on pineal 5-HTPD activity were mediated by sympathetic nerve impulses, these drugs might be expected to counteract them. Both bretylium and guanethidine abolished the effect of light on pineal weight (Fig. 1). Bretylium also eliminated the light-induced increase of pineal 5-HTPD activity, while guanethidine was without effect. It would appear from these results that these drugs, which interfere with nerve impulses, also interfere with some of the effects of light on the pineal gland, for example, weight. However, bretylium, but not guanethidine, abolished the effects of light on pineal 5-HTPD activity. Whether the failure of guanethidine to block the effects of light on pineal 5-HTPD activity is due to accessory effects of this drug, for example, amine depletion, cannot be ascertained from this work.

Light has now been shown to have a marked effect on two enzymatic processes in the rat pineal gland. It stimulates the activity of 5-HTPD, an enzyme which makes serotonin, and inhibits the activity of hydroxyindole-*O*-methyl transferase, an enzyme localized only in the pineal gland[17] which makes melatonin. It is interesting that the enzymatic synthesis of serotonin, a precursor of melatonin, is out of photic phase with the enzymatic formation of melatonin. Whether the effects of light on these two enzymatic processes are directly related remains to be established. The experiments described here and elsewhere[7,8] demonstrate that light information reaches the pineal gland and affects both enzymatic activities by the same anatomic pathway: the sympathetic nervous system. Since light also affects pineal weight via the sympathetic nervous system, it is possible that many other biochemical events in the pineal are regulated by light through this anatomic route.

Mechanism of the Antihypertensive Effect of α-Methyldopa

It has recently been reported that a decarboxylase inhibitor, α-methyl-3,4-dihydroxyphenylalanine (α-methyldopa), lowers the tissue norepinephrine level of various species of animals[1,2]. Moreover, this decarboxylase inhibitor has been demonstrated to be antihypertensive in man[3].

It seemed that these actions of α-methyldopa could be explained by the inhibition of decarboxylation of 3,4-dihydroxyphenylalanine (dopa). However, norepinephrine depletion produced by α-methyldopa continued long after the activity of the decarboxylase had been restored[1,2]. Thus the persistent effect on tissue norepinephrine appears to be due to another mechanism. Furthermore, as Clark stated previously in his review[4], substances which strongly inhibit the enzymatic decarboxylation of dopa *in vitro* do not always play parts as blood-pressure reducing agents *in vivo*. Therefore, not only the inhibitory effect of α-methyldopa on dopa decarboxylase as a direct result of tissue norepinephrine depletion should be considered.

Recently, we have become interested in the uptake and storage of catecholamines in various tissues. In the investigation recorded here, we have carried out model experiments on the uptake of norepinephrine by rabbit blood platelets and examined the effects of α-methyldopa and its decarboxylated metabolite, α-methyldopamine, on these processes. It was demonstrated that α-methyldopa was itself decarboxylated *in vivo*, in animals and in man[5,6].

As shown in Table 1, radioactive norepinephrine is taken up and accumulated by the blood platelets by an active transport mechanism. This uptake of norepinephrine was slightly inhibited by α-methyldopa and strongly inhibited by α-methyldopamine. It is of interest that we found α-methyldopamine to be much more potent than its corresponding amino-acid, α-methyldopa, in the inhibition of uptake of norepinephrine by blood platelets. Thus, it appears that the action of α-methyldopa is in large part, if not entirely, due to the amine derived from it metabolically. Reserpine, known as a catecholamine releaser, also strongly inhibited the uptake of norepinephrine by blood platelets, even at as low a concentration as 10^{-7}–10^{-9} M. It may be suggested that reserpine lowers the content of catecholamine in tissues primarily by blocking the uptake of amines into storage site. Further investigations have shown that the inhibitory effect of reserpine on the norepinephrine uptake has still remained even after reserpine had been removed from the medium. On the contrary, α-methyldopamine has an inhibitory effect when present in sufficient concentration in the medium. It seems that the action of α-methyldopamine might be of a 'reversible' type, rather than 'irreversible' as exemplified by reserpine. However, it is not yet known whether α-methyldopamine inhibits the uptake of norepinephrine into blood platelets by the same mechanism as reserpine does.

Table 1. Effect of α-Methyldopa, α-Methyldopamine and Reserpine on ^{14}C-Norepinephrine Uptake by Blood Platelets

	Norepinephrine uptake (c.p.m./mg of dry weight)	Inhibition %
Control (°C)	80	—
Control (37° C)	3,160	—
α-Methyldopa (10^{-3} M)	2,820	10
,, (10^{-4} M)	3,050	3
α-Methyldopamine (10^{-3} M)	630	80
,, (10^{-4} M)	1,170	63
,, (10^{-5} M)	2,040	36
,, (10^{-6} M)	2,750	13
Reserpine (10^{-6} M)	790	75
,, (10^{-7} M)	1,170	63
,, (10^{-8} M)	1,640	48
,, (10^{-9} M)	2,340	26

Rabbit blood platelets were suspended in 3 ml. of phosphate saline containing 12 μg of ^{14}C-norepinephrine (0·2 μc. of radioactivity) and different concentrations of each substance. The mixture was incubated at 37° C for 60 min. Values given represent the mean of six experiments.

Our results suggest that the depletion of tissue catecholamines produced by α-methyldopa is attributable to two factors. First, to the inhibition of an intermediate step in the biosynthesis of catecholamines. Secondly, catecholamines, synthesized from dopa, are prevented from being taken up by its storage sites by α-methyldopamine which is the decarboxylated metabolite of α-methyldopa. Thus there is an increase in the destruction of unbound catecholamines.

RADIOBIOLOGY

Variations in Radiosensitivity of a Mammalian Cell Line with Phase of the Growth Cycle

In recent years dose-survival curves have been published for a number of mammalian cell lines in culture following X-irradiation, and it is often assumed that the extrapolation number (n) and the 37 per cent survival dose (D_0) that characterize these curves are constants for a particular cell line. However, Lockart *et al.*[1] noted small differences in n and D_0 for different samples of HeLa *S*3 cells, and Bases[2] found that of two strains of HeLa cells only one gave consistent values of n and D_0. This communication describes variations in radiosensitivity with the phase of the growth cycle in rat sarcoma cells.

This cell strain was originally established in culture by Alexander and Mikulska from a benzpyrene-induced sarcoma in a *CBRI* rat; six months ago it was cloned in this laboratory. One of the clones (*S*6/1) was used for this work. The culture medium consists of calf serum (15 per cent) plus a 1 : 1 mixture of Fischer[3] and 199 media. Cultures were incubated in a water-saturated atmosphere of 95 per cent air and 5 per cent carbon dioxide at 37° C.

To prepare a series of bottles with the same initial inoculum of cells, approximately 5×10^5 cells in 100 ml. culture medium were divided equally between twelve bottles and left overnight. The cells were removed from one bottle with trypsin, counted in a hæmocytometer, re-suspended in culture medium and diluted to give concentrations of five and one thousand cells per ml. 1 ml. aliquots of the cell suspension were X-irradiated (140 kV, 5 m.amp, no extra filtration, 280 r./min) to total doses of 0, 300, 400, 500 r. (1,000 cells per ml.), 600, 700 and 800 r. (5,000 cells per ml.). The irradiated cells were plated into 35-mm plastic Petri dishes (Messrs. Falcon Plastics, Ltd.); 5 dishes per dose point, 10 dishes for controls. This procedure was repeated over the next 7 days at the intervals shown in Fig. 2. The Petri dishes were incubated for 7 days, fixed, stained and colonies counted with the aid of a low-power microscope.

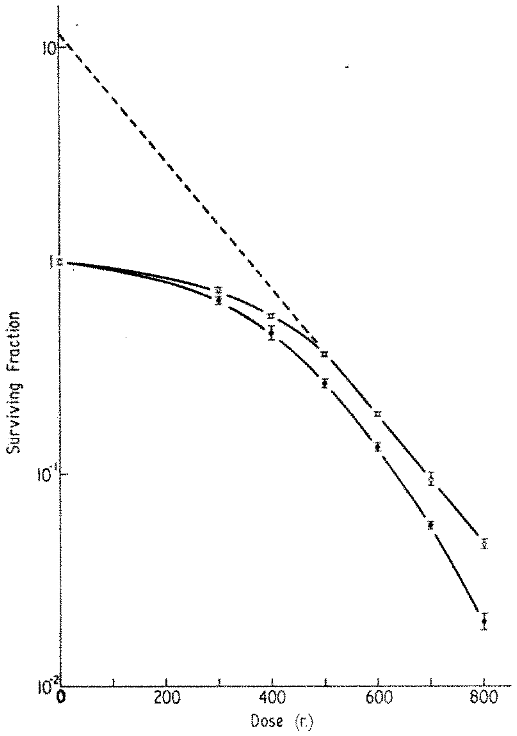

Fig. 1. Dose-survival curves for the *S*6/1 cells after X-irradiation. Upper curve (open circles) is for cells irradiated on the morning of the fourth day (lag phase): $D_0 = 144 \pm 3{\cdot}6$ r.; $n = 12 \pm 1{\cdot}3$; $7{\cdot}5 \times 10^5$ cells in the bottle. Lower curve (closed circles) for cells irradiated on the morning of the seventh day (stationary phase): D_0 estimated from the 700 and 800 r. points as 95 r. and n as of the order of 100; $2{\cdot}6 \times 10^6$ cells in the bottle. Vertical bars indicate *S.E.M.*

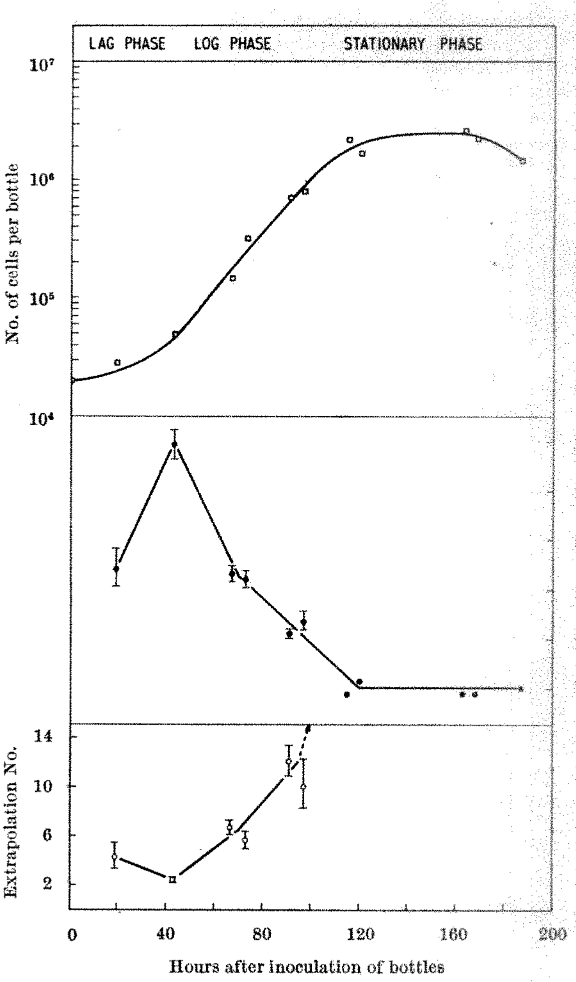

Fig. 2. Variations of D_0 and extrapolation number (n) of cells taken from different phases of the growth cycle. Abscissa, common to all three curves, is the time of trypsinization expressed as hours after inoculation of the bottles. The upper curve (open squares) is the growth curve—number of cells per bottle against time. The centre curve (closed circles) is a plot of D_0 against time. Vertical bars denote the standard errors; no errors are shown for values of D_0 corresponding to cells in the stationary phase, as these values were estimated from only two points (see text). Lower curve (open circles) is a plot of n against time; for cells in the stationary phase n can only be estimated but is of the order of 100. This steep rise in n is denoted by the dotted line and arrow

The dose-survival curves for cells irradiated on the first 4 days were of the typical form, that is, an initial shoulder followed by an exponential decrease in colony number with dose, whereas the curves for cells irradiated on the last three days showed a continuous curvature. Examples of these two types are shown in Fig. 1. Fig. 2 shows the values of n and D_0 plotted against the time of trypsinization (hours after inoculation of bottles). For comparative purposes the values of 'n' and 'D_0' for the last 3 days were estimated from the survival after 700 and 800 r. Fig. 2 includes a growth curve for these cells, that is, a plot of the number of cells in the bottle at the time of trypsinization against time; there was some loss of cells on the last day when they became overgrown and some detached from the glass.

It can be seen that the radiosensitivity fluctuates through the phases of the growth cycle. The value of D_0 is similar for cells in the middle of the lag and log phases. There is a pronounced maximum in D_0 as the cells pass through the lag to the log phase. A similar pattern was observed in a preliminary experiment. Cells in the stationary phase are the most radiosensitive and have the different type of survival curve described here. The extrapolation number follows a course that is the inverse of that of D_0.

Ludovici *et al.*[4] reported a difference in the radiosensitivity for HeLa cells irradiated in the lag and log phase of growth. Their criterion of radiosensitivity—change in cell count following irradiation—was shown by Glinos and North[5] to be unsatisfactory unless the growth of the cells after irradiation is followed for a time sufficient to eliminate the influence of 'doomed' cells. When this was done, these latter authors found no difference between this criterion and that of colony formation for mouse L cells. They also compared the radiosensitivities of these cells taken from the log and stationary phases and found no difference. However, the cells were irradiated some time after they had been plated when in both cases the cells may have been in the lag phase. Elkind and Sutton[6] reported a small decrease in D_0 for hamster cells in the log phase compared with cells in the lag phase which is compatible with the results shown in Fig. 2.

The fluctuation in radiosensitivity through the phase of the growth cycle is presumably related to changes in the metabolic state of the cells. The maximum in D_0 as cells pass from the lag to the log phase may be the result of an increased potential for repair. Increased rates of DNA, RNA and protein synthesis were found by Salzman[7] for HeLa cells at this point in the growth cycle.

If other cell lines show similar variations in radiosensitivity, care must be taken when comparing the radiosensitivities of different cell lines or of one cell line irradiated on separate occasions.

I wish to thank Dr. E. O. Field and Mr. K. B. Dawson for their assistance and advice.

Quantitative Relations between Doses of Chemical Protective Agents and Doses of X-irradiation

IN a previous paper[1] we quoted a number of results appearing in the literature which demonstrate quantitative relationships between the dose of protective agent and radiation dose. This applies especially to sulphydryl substances. In assuming that the sulphydryl protective agents act as radical scavengers this can be easily understood. Higher radiation doses may produce higher concentrations of radicals in the tissue and for this reason the concentration of radical scavengers must also be higher. Contrary to this, high radical scavenger doses may have relatively less protective effect in lower radiation doses. The increase rate of the protective effect of such agents is larger for higher radiation doses than for lower ones.

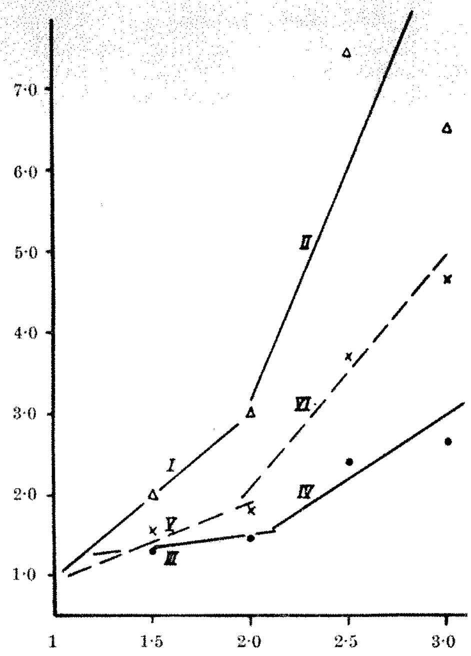

Fig. 1. Curves of the increase rates after whole-body X-irra 810, 750 and 690 r. Abscissa: doses of the intraperitone cysteamine in mg/mouse. Ordinate: Dx/D_1 = percenta animals at the cysteamine dose x divided by the percent animals after application of the lowest cysteamine dose, mouse. The regression lines were computed by the formul $y - y_1 = \frac{y_2 - y_1}{x_2 - x_1}(x - x_1)$ and the mean lines drawn

△, 810 r.; ×, 750 r.; ●, 690 r.

In contrast to these ideas the possible behaviour of pharmacodynamically acting protective substances is to be discussed. Here the radical-quenching effect mechanism is not present, but, for example, changes in the blood circulation in radiosensitive organs are observed[3]. It is assumed that in the usual conditions there are no dose relationships between the protective agent and the radiation dose. If our assumption were correct, considerable differences would exist in the increase rate tective effect of radical-quenching substance which act on the basis of their pharmacodynan

As typical substances for both possibiliti chosen cysteamine as a radical scavenger[2] an as a pharmacodynamically active substance[3]. ments were carried out with male mice (19–21 g inbred strain. In the experiments with cyst mice received 690, 750 and 810 r., respectiv body irradiation. The protective effects of th doses of cysteamine were tested for each radi 1·0, 1·5, 2·0, 2·5 and 3·0 mg/mouse 5 min bef tion intraperitoneally. Each group of these and those with histamine was carried out with of 50 and a maximum of 200 animals. In th investigations the radiation doses applied 950 and 1,000 r. respectively. The correspond histamine were: 0·5, 1·0, 2·0 and 5·0 mg hista 5 min before irradiation intraperitoneally.

In order to find the increase rate of the tw agents the percentage of living animals after each radiation- and agent-dose was divided b sponding lowest dose of the protective agent. the relation D_x/D_1 was found; D_x stands for higher doses, and D_1 for the lowest one, of the

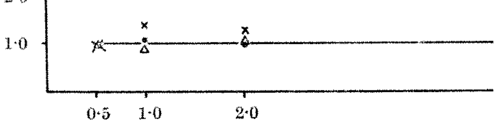

Fig. 2. Curve of the increase rate after whole-body irra 1,000, 950 and 810 r. Abscissa: doses of the intraperiton histamine in mg/mouse. Ordinate: Dx/D_1 corresponding lowest dose of histamine (D_1) is 0·5 mg/mouse. The re has been computed and drawn out corresponding t

tective agent. The relationship between D_x/D_1 (ordinate) and the different doses of the protective agents (abscissa) is shown in Figs. 1 and 2.

Fig. 1 shows the position after application of cysteamine. Between the doses of 1 and 2 mg the increase rate grows only a little in the three cases of 810, 750 and 690 r. The turning point is found at 2 mg. From here it is clearly demonstrated that the increase rate becomes much bigger in the case of 810 r. than in that of 690 r. The differences are statistically significant. For this reason, an increase of protective agent produces an increase in the protective effect in the case of cysteamine. In the lower dose range this effect is only very small; the increase rate directly depends on the radical concentration in the tissue. In other words, the dose of the protective agent and the radiation dose are closely related, thus confirming our assumption.

In Fig. 2 the findings of the histamine experiments are illustrated in the same manner. It is possible to demonstrate for all radiation doses and for all doses of histamine that there is no growing increase rate. The increase rate (D_x/D_1) is one or nearly one in all cases. The explanation for this is that the pharmacodynamic action of 0·5–5·0 mg histamine is sufficient to produce the optimal protective action for all radiation doses.

The experiments demonstrate the differences in the mode of action of various chemical protective agents, and would seem to make clear the mode of action of chemical protective agents, at least certain ones.

Efficient Labelling of Tissue-soluble Proteins with Iodine-131 using Chloramine T

Following the reports of Hunter and Greenwood[1] and Reith and Tampion[2], the chloramine *T* radioiodination procedure has been applied[3,4] for labelling, with iodine-131, serum proteins from several animal species. High labelling efficiency (about 65 per cent) could be obtained provided oxidation was allowed to proceed for at least 30 min. The advantage of using a protein: chloramine *T* ratio of about 250 : 1 has been stressed[3,4] in order to avoid even small damage to the proteins, undetectable by electrophoretic and immunological analyses but evident from metabolic behaviour *in vivo*.

Because of its utility in disposing of tissue-soluble ^{131}I-proteins an attempt to adapt the procedure for labelling with radioiodine tissue-soluble proteins has been made and results are reported here.

Selected organs were removed from saline-perfused animals and homogenized with an equal volume of 0·15 M phosphate buffer, *p*H 7·6. The homogenates, after having been frozen at −30° C and thawed six times, were centrifuged at 34,000*g* for 60 min, and the supernatants were filtered through paper. Half of each tissue-soluble protein solution was dialysed in 'Visking' tubing 8/32 in. for 2–3 days. The whole procedure was carried out at +2°. After dialysis both protein solutions were again centrifuged (3,000*g*, 90 min) and adjusted with phosphate buffer at the same protein concentration. Proteins were estimated either by the method of Gornall *et al.*[5], or by micro-Kjeldahl procedure.

The final procedure adopted was as follows: to a solution (1·0 ml.) of tissue-soluble proteins (13–31 mg) was added 0·15 M phosphate buffer (*p*H 7·6) containing the required amount (0·025–0·5 mc.) of carrier free iodine-131 (*IBS*. 3, the Radiochemical Centre, Amersham) and then chloramine *T* solution (B.D.H.; 10·0 mg/ml. in *p*H 7·6 phosphate buffer). The test tube was stoppered with 'Parafilm', gently shaken and, in order to increase labelling efficiency[3,4], oxidation was allowed to proceed for 60 min. At this stage the proteins were diluted 3·5 times. Afterwards sodium metabisulphite solution (6·25 mg/ml., w/v solution in *p*H 7·6 phosphate buffer) and carrier sodium iodide (0·2 ml. of a 10 per cent solution) were added separately with mixing. 0·50–0·62 mg of freshly prepared sodium metabisulphite was sufficient to prevent any iodination due to 1·0 mg of chloramine *T*. The reducing agent was in slight excess in order to avoid over-iodination on adding carrier iodide.

The reaction mixture was made up with proteins in phosphate buffer containing 0·5 mc. iodine-131 per each sample. Percentages of ^{131}I-TPA soluble radioactivity were estimated on the eluates before and after dialysis.

* Each value, except when chloramine was not added, is an average of at least two determinations.

The reaction mixture, after having been counted to determine the total radioactivity, was passed through a

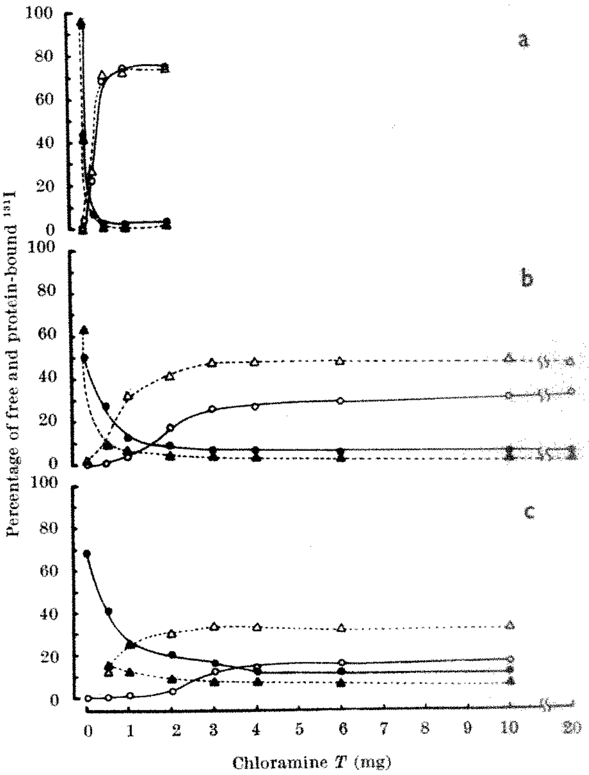

Fig. 1. Rabbit serum (*a*), liver (*b*) and kidney (*c*) ^{131}I-protein recoveries using the chloramine *T* procedure. Percentages of total iodine-131 recovery of undialysed (○) and dialysed (△) protein samples. Percentages of ^{131}I-TPA soluble radioactivity of undialysed (●) and dialysed (▲) samples. The reaction mixture was made up with proteins in phosphate buffer containing 25 μc. iodine-131 per each sample

column (8·0 × 1·0 cm) of the anion-exchange resin 'De Acidite FF' in the chloride form. The eluates, including two 0·15 M sodium chloride washings, were counted to ascertain the percentage recovery of radioactivity. To attain higher recoveries the exchange resin columns were presaturated with 5–10 mg of tissue soluble proteins. If necessary, protein solutions were concentrated by dialysis[6].

^{131}I-tungsto-phosphoric acid (TPA, final concentration: 1·7 per cent in 0·68 N hydrochloric acid) soluble radioactivity as percentage of the original radioactivity was measured in a well-type scintillation counter in the presence of carriers NaI and bovine serum proteins (35 mg).

Labelling efficiencies were lower for rabbit liver and kidney soluble proteins compared with those for serum proteins, particularly if protein solutions were not dialysed, due perhaps to presence of reducing agents (Fig. 1). However, dialysis of serum proteins was not beneficial. No binding of iodine-131 to proteins was observed if chloramine *T* was omitted. An inverse relationship is apparent between labelling efficiency and ^{131}I-TPA soluble radioactivity.

It may be observed that by increasing the amount of chloramine *T* (over 3–4 mg) the labelling efficiency is reduced. The increase in oxidizing agent determined, after addition of sodium metabisulphite, the appearance of an increasingly intense opalescence and of visible protein aggregates in the protein solution. The radioactive larger aggregates trapped by the exchange resin, or discarded after centrifugation, lowered the recovery. Either chloramine *T* or sodium metabisulphite or carrier iodide used singly were ineffective.

Labelling efficiency is diminished by using the same amount of oxidizing agent but higher protein concentration.

31–53 per cent of ^{131}I-protein-bound was obtained by labelling dialysed samples with 0·5 mc. of iodine-131. Only soluble proteins from rat kidney were scarcely labelled (Table 1). After removing most of the iodide-131 by ion-exchange resin, dialysis can further reduce the unbound radioactivity.

Rabbit and rat protein samples (of Table 1) were tested by starch-gel electrophoresis[7] and a contact autoradiogram of the bottom slice was taken with X-ray film ('Kodirex'). Radioactivity appeared bound to tissue proteins, prealbumin, albumin and globulin-like components. Immunological examination of rat and rabbit protein samples showed little or no contribution of serum proteins to tissue soluble proteins.

By using the chloramine *T* procedure the distribution and fate of soluble ^{131}I-proteins from rabbit and rat liver have been studied[8].

BIOLOGY

Mating Preferences in Wild Birds

Hayman[1], describing mating preference in a merino ram, states that mating preference has long been postulated as a mechanism concerned in the development of new species, but that such preference does not appear to have been observed in wild-type populations.

Mating preference has, in fact, been demonstrated among at least three species of polymorphic birds. Populations of the snow goose, *Chen caerulescens*, are polymorphic for plumage colour: individuals may be blue or white. Strongly assortative mating (mating of like phenotypes) has been demonstrated in wild populations of this species[2]. The arctic skua, *Stercorarius parasiticus*, has a pale- and a dark-plumaged form, and assortative mating among these forms has been demonstrated in at least some wild populations[3]. In the white-throated sparrow, *Zonotrichia albicollis*, there are two colour forms, one with a brownish and the other with a white crown stripe. In this species, strongly disassortative mating has been demonstrated[3].

In general, assortative mating increases and disassortative mating decreases the genetic variance of a population. But whether mating preference is important in sympatric speciation remains to be shown. Theoretically, complete or nearly complete assortative mating could give rise to new species within a single population.

Evidence for a Dynamic Equilibrium in the Incidence of Cestoda and Acanthocephala in the Intestines of Freshwater Fish

As Hopkins observed[1], following an examination on the seasonal variations in the incidence and development of the cestode *Proteocephalus filicollis* (Rudolphi, 1810) in the stickleback *Gasterosteus aculeatus* L., the significant point in the host–parasite relationship, usually overlooked, is that the incidence of the parasite in the host throughout the year is a dynamic equilibrium. Hopkins clearly showed that less than 1 per cent of the worms which became established in the intestine of the stickleback survived to become gravid. Thus, from the evidence, Hopkins deduced that the parasite population in the intestine of the stickleback was in dynamic balance, that is, the resultant point of equilibrium was the product of gain and loss of worms from the host.

A similar dynamic situation was postulated by Chubb[2] for the life of the cestode *Triaenophorus nodulosus* (Pallas, 1781) in the intestine of the pike *Esox lucius* L. The results in this instance were complicated by difficulties in obtaining sufficient pike of each length group, and by changes of diet of the pike in relation to length. Nevertheless, it was clear that the parasite population was in dynamic balance. Data on the occurrence of the acanthocephalan *Echinorhynchus clavula* Dujardin, 1845, nec. Hamann, 1892, in the fishes of Llyn Tegid[3] also indicated the presence of a dynamic equilibrium between gain and loss of worms.

Recently, additional evidence for a dynamic equilibrium in the incidence of Acanthocephala in the fish host has become available.

During a study on the parasites of the brown trout *Salmo trutta* L. in the Afon Terrig, North Wales[4], particular reference was made to the biology of the acanthocephalan *Echinorhynchus truttae* (Schrank, 1788). Experimental infections of *E. truttae* were established in the brown trout and the rainbow trout *Salmo gairdneri* Richardson, and movements of the worms were found to occur in the intestines. It was found that the acanthocephalans were first attached in the pyloric region of the intestine, and occupied a more posterior region of the intestine as they matured; gravid females were found in the rectal region[4]. A similar observation has recently been recorded for *Acanthocephalus jacksoni* Bullock, 1961 (ref. 5). In addi-

Thermal Precipitator

Short period sampler of dust particles up to 20 μ diameter. Aspiration rate 7 ml./min.

Long Period Dust Sampler

Long period sampler of particles below 7 μ diameter (the respirable range). Aspiration rate 2 ml./min.

Cascade Impactor

Samples liquid or solid particles within size range 0.5 to 50 μ with size separation into 4 fractions during sampling. Aspiration rate 17½ litres/min.

Hexhlet

Samples large quantities of the respirable fraction of a dust cloud (below 7 μ) for subsequent chemical analysis or weighing. Aspiration rate 50 litres/min.

Personal Air Sampler

Long period sampler of radio-active particles in the breathing zone of the wearer. Can also be used for sampling other toxic substances or gases. Aspiration rate 2 litres/min.

Plutonium Dust Sampler

For fast sampling of toxic airborne contaminants such as plutonium dust, or for sampling large volumes of relatively dust free air. Aspiration rate 1000 litres/min.

Airborne Bacteria Sampler

Samples bacteria from a known volume of air for subsequent counting after incubation. Aspiration rate 28 litres/min. with small sampling box, or 700 litres/min. with large sampling box.

Hirst Spore Trap

A long period sampler of airborne spores and pollens for their subsequent counting and identification. Aspiration rate [illegible] litres/min.

ion to a loss of spent males from the trout, female *E. ruttae* at all stages of maturation and immature males were passed out in the fæces at irregular intervals. In this connexion it was interesting to note that in trout autopsied immediately after killing with a blow on the head, a number of *E. truttae* of both sexes were found free in, or attached to, the contents of the intestinal lumen. It thus appears that movement of position of the acanthocephalans in the intestine of the host may be a regular phenomenon, and may be an important factor in the loss of worms from the host.

As worms were passed from fish experimentally infected and kept in an artificial environment, it might be thought that the conditions in which these fish were maintained were contributory to the loss of the worms. While this point cannot be ignored, it is probable it is not of major significance. In this connexion, it was of interest to note the finding of specimens of *Acanthocephalus lucii* (O. F. Müller, 1776) in a general limnological sample collected in the Grand Canal, County Dublin, Eire, on September 18, 1963. Two worms, a male and an ovarian ball stage female, were taken, which indicates a loss of Acanthocephala from their hosts even in natural conditions.

While the loss of gravid and spent worms is understandable, the factors evoking the passing out of immature forms, of both sexes, are not known. It is clear that the evidence indicates that the phenomenon of a dynamic equilibrium between gain of worms from the intermediate host, and loss of worms from the intestine of the definitive host, is found in some species of Acanthocephala and Cestoda of freshwater fishes. It seems probable this phenomenon is of wide occurrence, although it has rarely been commented on by previous workers.

Transmission of Pig Lungworms (*Metastrongylus* sp.)

THE life-cycle of the pig lungworm (*Metastrongylus* sp.) has been known since Hobmaier and Hobmaier[1] incriminated earthworms as the obligatory intermediate host. Lungworm infestation in pigs is therefore likely to be a problem only where animals have access to pasture and hence earthworms.

A recent survey (1961–63) at a North Wales abattoir showed that the incidence of lungworms in pigs varies from 8 to 65 per cent of pigs examined, the figure depending on the season. The majority are *M. apri* (syn. *M. elongatus*), *M. pudendotectus* being very rare.

During an investigation of the effects of lungworms on pigs a litter of seven minimal disease Welsh pigs (obtained by hysterectomy) were penned in groups of three (Nos. 1, 2 and 3) and four (Nos. 4, 5, 6 and 7) in accommodation which excluded earthworms. Pigs 2, 3 and 4 were then separately isolated and fed an initial infective dose of 4,000 infective larvæ in a gelatine capsule. The larvæ had been removed from earthworms by dissection. After infection the pigs were given food and water in an attempt to ensure that the infective dose had been cleared from the mouth, then returned to their pens and the company of their litter-mates.

The three infected animals started to cough 10 days after the date of infection, and the first lungworm ova were detected in the fæces by the flotation technique of Dunn and White[2] 32 days after infection. Fæcal samples of uninfected animals were negative and the animals did not cough.

Clinical symptoms of coughing were more severe in the minimal disease pigs we have kept than in similarly housed non-minimal disease animals and a bout of coughing always preceded the effort to come to the trough at feeding time. Fifty days after the initial infection, besides retaining their cough, the infected animals developed the habit of vomiting shortly after they had ingested the first few mouthfuls of food at feeding times, the convulsions continuing until all the ingested material was regurgitated. The vomited material was always eagerly devoured by all other pigs in the pen. This has not been observed in other infected animals but the pigs described here retained this habit until slaughter.

Sixty-eight days after infection, pigs 2 and 3 were re-infected with 2,500 larvæ. Twenty-nine days after re-infection, pig 3 showed an increase in fæcal egg counts, in contrast to a previous experiment where much larger re-infection doses were used and very few lungworm eggs were recovered, presumably because the animals had become immune. Pig 2 showed no increase in fæcal egg counts although eosinophilia indicated that at least a few infective larvæ had invaded the host as a result of the re-infection. At this time, however, the supposedly uninfected animals yielded fæcal samples that were positive for lungworm ova (2–5 eggs/g fæces), these being passed until slaughter. These animals developed a slight cough and eosinophilia and skin sensitization tests were positive.

Pigs 2 and 3 were re-infected again with 2,500 larvæ 43 days after the first re-infection. These worms did not have time to mature and produce eggs, since the pigs were killed 2 weeks later, but a few did reach the lungs. Table 1 details the numbers of lungworms fed and those recovered from all animals at slaughter.

Table 1

	Pen 1			Pen 2			
Pig No.	1	2	3	4	5	6	7
No. larvæ dosed							
Initial dose	0	4,000	4,000	4,000	0	0	0
First reinfection	0	2,500	2,500	0	0	0	0
Second reinfection	0	2,500	2,500	0	0	0	0
No. of worms recovered from the lungs at slaughter	46	74	233	42	10	51	5

In previous experiments where pigs were individually penned the control animals did not become infected, but Table 1 shows that lungworms may be passed from one pig to another when pigs are housed together. Just how this comes about is a matter of speculation at the moment but three possibilities may exist: (*a*) that infective larvæ are retained in the stomach of the experimentally infected animals for some time after their introduction through the mouth and later regurgitated and made available to other animals; (*b*) that infective lungworm larvæ are passed through the gut of the infected pigs and become available to other animals from the floors of the pens or in contaminated food and water; (*c*) that infective larvæ having migrated to the lung of the host may then be passed to a second pig in saliva or sputum.

The habit of regurgitation developed in infected animals meant that when animals 2 and 3 were re-infected the chances of viable infective larvæ being vomited were high and possibly this accounts for the infection in pig 1. This could not account for the infection of three extra animals in the second pen from pig 4 because this was not re-infected, and indeed the size of the lungworms recovered at post-mortem from these control pigs and pig 1 suggests that infection had occurred much earlier than the date of re-infection.

One cannot discount the second possibility, for the ultimate burden of worms is very much lower than the initial dose and might suggest losses with the fæces. This phenomenon has been frequently observed by other workers in the past in that the number of worms successfully invading and completing development in a host compared with the dose fed is often very low.

The frequency of this type of transmission of lungworm from one animal to another is a matter of some conjecture, but it may explain how the disease is transmitted to animals which have not had access to the earthworm intermediate host.

It is conceivable that the foregoing methods of transmission may apply to other parasites and hosts, and this is not difficult to visualize among ruminant animals when they lick each other mouth to mouth. Indeed, this is the known method of transmission of rumen protozoa from adult animals to young stock.

Isolation and Bioassay of a Fungal Morphogen

THE staling of fungal cultures is a topic which has not received much attention recently. Pratt[1] described two types of staling agent, organic acids and potassium bicarbonate. She suggested that staling due to the formation of bicarbonate by the carbon dioxide of respiration is of primary importance and occurs whenever the medium is such that a basic radical is set free. She determined that the organic acid radicals were not effective as staling agents in the alkaline-staled medium. Pratt investigated the staling of a species of *Fusarium* in Richards's solution and her criterion of staleness was based on the average germ-tube length of conidia of *Botrytis cinerea* sown in drops of the filtered medium in which the *Fusarium* had grown. More recently Park[2] has investigated staling in *F. oxysporum* using agar cultures of *Aspergillus niger* as the test organism. Drops of culture medium were pipetted on to the margin of colonies of *A. niger* and the criterion of staleness was the cessation of extension-growth of the marginal hyphæ with accompanying vacuolation. Vacuolation has since been adopted as the best indication of ageing, since, whereas the stale culture fluid would always induce vacuolation, extension-growth was not permanently inhibited under all conditions of test. It is also important to note that a wide range of substances will cause hyphæ to branch or to cease extension-growth, but no substance among several tried has yet been found to reproduce the vacuolation effect caused by the stale medium from which the bulk of the mycelium has been removed by filtration through nylon gauze. It is of additional interest that both extracts of soil and of pond-water can also induce vacuolation of our test organism. The substance or substances responsible may therefore be associated with microbial habitats of different sorts.

Vacuolation is normally considered an indication of senescence in fungal hyphæ and so the factor causing vacuolation may be of importance in the consideration of morphogenesis, since a few minutes after its application it induces this symptom of ageing and other morphological effects of maturation in the juvenile hyphæ of the test organism. The present report gives a brief description of the method of assay used for the detection of the factor and methods so far utilized for its purification.

The standard producer fungus for the vacuolation factor in these investigations has been *F. oxysporum*, but under the same conditions of culture the effect has been found to be given by isolates of *F. moniliforme*, *F. culmorum* and *F. solani*, and also by *Trichoderma viride* and *Penicillium expansum*. The test organism used is *A. niger* grown for 3–4 days at 25° C on the agar medium described by Park[2]. Drops of the solution to be tested are pipetted on to the colony margin so as to wet the hyphal tips which are then examined under the microscope for cessation of extension-growth and for the appearance of vacuolation beginning near the tips and extending back.

The time to appearance of vacuolation after application of the culture filtrate gives some measure of the activity of the factor. The temperature of the test culture affects this time. The time to vacuolation is at a minimum at 25°–30° C and increases with lower temperature. The times recorded from one such experiment were from 3·5 min at 25° to 14 min at 4° C. Dilution of the culture filtrate increases the time to vacuolation. A solution giving vacuolation in 2·5 min gave vacuolation in 16 min when diluted to 1/24. Further dilution allowed extension-growth to continue and there was no vacuolation. The time to appearance of vacuoles in treated hyphal tips is influenced also by other materials present in solution. Glucose, for example, at a concentration of 0·001 per cent (w/v) gives a smaller time to vacuolation than that in the absence of glucose. Increasing the glucose concentration over the range 0·001–1·0 per cent gives a progressive decrease in the time to vacuolation, that is, increases the rate of action of the factor.

The *p*H of the culture filtrate has a marked effect on the response of the treated hyphæ. Normally the *p*H of the culture filtrate is 3·2, and at this *p*H cessation of extension-growth occurs within about 1 min. The first stages of vacuolation together with the cessation of particulate movement in the cytoplasm are observed at 2–3 min. The extent of vacuolation increases for a further 3 min and the condition then remains static for some time. Further growth arises by the origin of lateral branches behind the affected portion. The extent of vacuolation is smaller at a higher *p*H and the lateral branches arise sooner and closer to the tip. At *p*H 8 no vacuolation occurs, but there is cessation of extension-growth at the original growing point and a slight swelling of the tip. Usually two, but sometimes three, small protuberances become visible after about 10 min just behind the original growing point. These rapidly grow out as new sub-apical branches giving a sympodially branched structure.

An effect of the factor on spore germination has been demonstrated. Uninoculated culture solution is inappropriate as a control for these experiments because its nutritional level is higher than that of a culture filtrate. A suitable control solution is prepared by adsorbing the vacuolation factor from the culture filtrate with activated charcoal and then filtering through paper. Culture filtrate treated in this way should not be nutritionally more favourable for germination than a similar solution not treated. Germination of spores incubated in the active culture filtrate is not totally inhibited, but a lower germination rate than that in the control has been demonstrated in sporangiospores of *Absidia glauca*, *Mucor hiemalis*, *M. plumbeus*, *Rhizopus stolonifer* and *Zygorhynchus vuilleminii*, in conidia of *Alternaria tenuis*, *F. caeruleum*, *F. solani* and *Stemphylium lanuginosum*, and in icospores of *Chaetomium globosum*. Sporangiospores of *unninghamella elegans*, and conidia of *Botrytis cinerea*, *. culmorum* and *T. viride*, showed no detectable reduction germination in active culture filtrate. Sporangiospores *R. stolonifer* were germinated in a control solution for h to 4 per cent and for 5 h to 8 per cent germination-vels, and then transferred to active culture filtrate. ermination-levels of the transferred spores remained onstant and there was no increase in germ-tube length ver a period of 22 h. Thus, whereas spores incubated hroughout in active culture filtrate were able to germin-te, although more slowly than in control solution, artially germinated spores were completely inhibited fter transference to active culture filtrate.

In order to produce large quantities of the vacuolation actor it is convenient to culture *F. oxysporum* in 20–40 l. atches in the light at 20°–22° C with constant aeration. 'he medium used has the following composition; glucose, ·0 g; $MgSO_4.7H_2O$, 0·5 g; KH_2PO_4, 0·2 g; NH_4NO_3, ·1 g, distilled water to 1 l. Under these conditions the acuolation factor can be demonstrated after five days of ulture. It is convenient to filter the culture medium hrough a fine nylon gauze to remove most of the mycel-um. The filtered medium can be concentrated to 1/20th ts original volume by vacuum distillation, and the *p*H fter concentration is 2·8. The *p*H of the medium is djusted to 10·0 with 0·1 N sodium hydroxide solution nd the medium extracted with diethyl ether. The *p*H s then adjusted to 3·0 with 0·1 N hydrochloric acid and he medium again extracted with ether. Bioassay of hese fractions indicates that the active factor has acidic roperties since no activity is detected in the basic- and ieutral-ether fraction, but the amount of activity present n the acidic-ether fraction is equivalent to that in the riginal culture filtrate.

It was important to know whether vacuolation was lue to one or more closely related substances or several nrelated substances. It was considered that counter-urrent fractionation would give an indication as to whether more than one substance was involved. An cidic-ether extract from 2 l. of filtered medium was listributed between diethyl ether and 0·02 M phosphate ouffer (*p*H 6·1) for 50 transfers in a counter-current pparatus. Both the aqueous and ethereal phases from each tube were bioassayed for vacuolation activity. Marked activity was present in both the aqueous and ethereal phases of tubes 7–11 (inclusive) with peak activity in tube 9. Very minor activity occurred in the aqueous phase of tube 1 and in the ethereal phases of tubes 44 and 45. The main vacuolation effect can thus be ascribed to one or more related substances which are acidic in nature.

Perhaps the main difference between staling under our conditions and those of Pratt is that, whereas the culture filtrate she used was fairly alkaline, that used at Belfast is acidic. Consequently, bicarbonates are certainly not a contributing factor to cultural staling in *F. oxysporum* under our conditions. It seems likely that our factor is composed of one or more acidic substances. Moreover, the factor has been shown to be less effective at alkaline *p*H in our assay. It is significant that the factor described in this communication is produced by several unrelated fungi and also exists in some natural microbial habitats. A number of fungi also respond to the factor in a similar way to *A. niger*, and the factor isolated from the culture filtrate of *F. oxysporum* will cause vacuolation and cessation of extension-growth when applied to young cultures of *F. oxysporum*.

Formation and Metabolism of Lactic Acid during Germination of Pea Seedlings

EARLIER work[1-4] has indicated that the production and metabolism of ethanol during the germination of pea seeds are accompanied by changes in the organic acid contents of the cotyledons. Paper chromatography of the organic acid fraction[3] showed that, in addition to large changes in the malate content, the amounts of lactic acid fluctuated as ethanol was formed and metabolized.

In the work recorded here, changes in the lactic acid content of germinating peas have been examined in more detail. In addition, slices of pea cotyledons have been supplied with micromolar amounts of lactate-1-^{14}C to determine whether the changes observed in lactate content during germination were due to the metabolism of this compound. Such experiments have indicated that temporary increases in the lactate content occur during the earliest stages of germination. With emergence of the radicles, the amounts of lactic acid are decreased and the cotyledons are able to metabolize supplied lactate-1-^{14}C. After short periods of incubation with lactate-1-^{14}C, the cotyledons incorporated the carbon-14 into carbon dioxide, amino-acids and organic acids. Extracts of the cotyledons suggest that lactate metabolism is due to activity of a lactic dehydrogenase system located in the mitochondria.

Pea seeds, variety 'Homesteader', were germinated in vermiculite[4]. Samples of the seeds were removed daily over a five-day period and killed in ice-cold 10 per cent trichloroacetic acid. After adjustment to *p*H 8, the lactic acid contents were determined by the colorimetric procedure of Barker and Summerson[5]. Following the initial 18-h soaking period, the seeds contained 105 μmoles of lactate/100 g fresh wt. This increased to a maximum of 120 μmoles/100 g fresh wt. after 10 h germination and fell abruptly to 40 μmoles/100 g fresh wt. when the radicles had emerged.

In the experiment shown in Table 1, samples of peas, in which the lactate content was decreasing, were supplied with lactate-1-^{14}C solutions. The cotyledons were sliced[3] and placed in buffered lactate-1-^{14}C solutions as indicated. At the end of the experimental period, the tissues were killed in boiling 80 per cent ethanol and, following homogenization, were extracted using dilute ethanol and water. The soluble material was then separated into four fractions using ion exchange columns[4]. The organic acids were further separated by the method of Palmer[6]. The radioactivity of the fractions separated was assayed using a 'Mylar' window continuous gas flow Geiger–Müller tube.

It is evident from Table 1 that the small amounts of supplied lactate-1-^{14}C were rapidly metabolized. After 5 min of lactate-1-^{14}C metabolism, glutamic and aspartic acids contained five times as much radioactivity as the carbon dioxide released. Furthermore, small amounts of carbon-14 were detected in the acids of the tricarboxylic acid cycle, especially malate. These results might indicate a rapid fixation of carbon dioxide derived from the 1 position of the lactate-1-^{14}C supplied. Similar small amounts of $^{14}CO_2$ have been observed when ethanol-1-^{14}C

Table 1. METABOLISM OF LACTATE-1-^{14}C BY PEA COTYLEDON SLICES*

Fraction	Incubation time (min) 5 ^{14}C (c.p.m.)	10 ^{14}C (c.p.m.)	20 ^{14}C (c.p.m.)	30 ^{14}C (c.p.m.)
Organic acids				
Glycollate fraction	225	230	260	270
Succinate	590	860	1,100	1,200

Pyruvate	1,600	3,200	5,400	7,800
Sugars	Not active	2,000	4,400	8,000
Amino-acids				
Glutamic and aspartic	1,500	8,000	14,000	19,000
Neutral and basic	10,000	26,000	31,000	40,000
Carbon dioxide	300	1,440	7,000	14,000
Total ^{14}C incorporated	15,200	42,780	64,260	91,420

* 0·5-g samples of 3-day-old pea cotyledons sliced and incubated at 30° C in darkness with 0·82 μmoles lactate-1-^{14}C (2·5 μc. of ^{14}C) in 50 μmoles phosphate buffer at *p*H 5·5.

was fed to these tissues[4]. Furthermore, feeding $^{14}CO_2$ to these tissues has indicated that organic acids and amino-acids are readily synthesized by a process of dark carbon dioxide fixation[7]. Paper chromatography of the neutral and basic amino-acid fraction[4] revealed the presence of alanine-^{14}C. Degradation[8] of samples of alanine formed during lactate-1-^{14}C feeding indicates that approximately 92 per cent of the radioactivity is located in the 1 position. These results are therefore consistent with an oxidation of lactate-1-^{14}C to pyruvate-1-^{14}C which would then yield alanine-1-^{14}C by a transamination reaction. Pyruvate-^{14}C is present in the organic acid fractions in large amounts, and mitochondria, isolated in sucrose-phosphate buffer[9], readily form pyruvate-^{14}C and $^{14}CO_2$ when supplied with lactate-1-^{14}C.

More detailed experiments on lactate metabolism in these and other plant tissues are now in progress. This work was supported by National Research Council grant A-1747.

CYTOLOGY

Chromosome Abnormality in Three Cases of Lymphatic Leukæmia in Cattle

In three cases of overt lymphatic leukæmia in cattle a very specific change in the chromosome complement has been found.

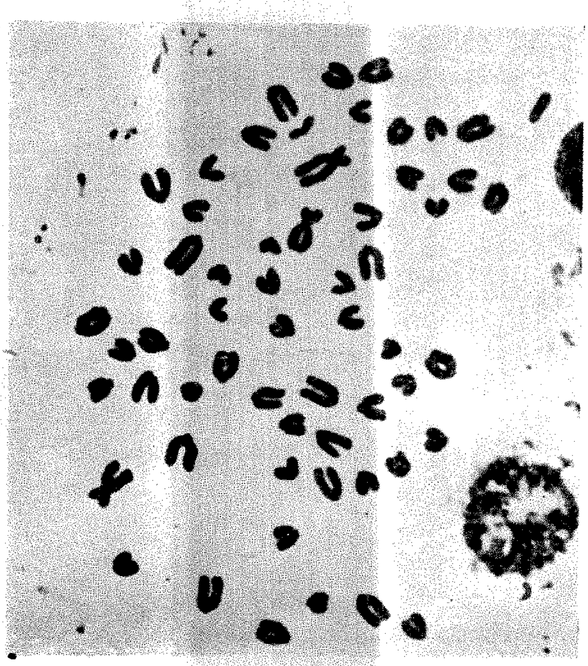

Fig. 1. The mitotic chromosomes of a leucocyte in one of the cases. (× c. 1,600)

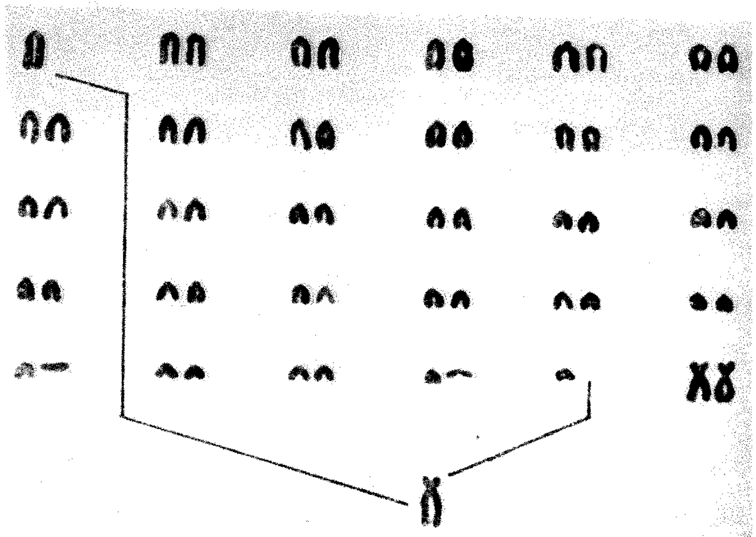

Fig. 2. The karyogram with the autosomes arranged as nearly as possible according to decreasing size. The lines show the origin of the abnormal chromosome

Sedimentation of the erythrocytes in the blood sample was obtained after centrifuging at 1,000 r.p.m. for abou 15 min. Leucocytes and serum were removed and sus pended in tissue culture medium Parker 199. Phyto hæmagglutinin was added just before incubation. Eve on the second day, many leucocytes were in mitosis The cells were treated with colchicine and hypotonic flui and were fixed in 9 parts 60 per cent acetic acid plus part 0·1 N hydrochloric acid. After staining with aceto orcein, manual squash preparations were made in th usual way.

More than 100 mitoses from every animal were analysed and all were found to contain 59 chromosomes, with on diverging morphologically from the normal complemen (Fig. 1). This chromosome had a subterminally situate centromere and presumably originated from a chromosom fusion or translocation, the real nature of which cannot a yet be established. The chromosome pairs affected ar numbers 1 and 29, the largest and the smallest pair, fact that has been confirmed by chromosome measure ments (Fig. 2).

The same chromosome abnormality was found in fœtus from one of the cows. The fœtus was about si months of age and looked normal. Mitoses obtaine *in vivo* from the bone marrow and chromosomes of kidne cells after eight days incubation were examined.

Electron Microscope Observations on Mitotic Chromosomes in Erythroblasts of the Newt, *Triturus cristatus cristatus*

The structure of DNA is now known and the externa form of mitotic chromosomes of higher organisms i fairly well characterized in the light microscope. However the way in which chromosomes are constructed from DNA histones and other proteins is not yet clearly understood although there are many observations and several theories of chromosome structure[1-9]. In chromosomes of new erythroblasts we have found structures, intermediate in size between DNA molecule and chromosome, which may provide clues to the way these chromosomes are organized

Pieces of newt spleen were fixed in buffered glutaraldehyde and OsO_4 (ref. 10) and embedded in 'Araldite'. Sections were stained in uranyl acetate and lead citrate and examined in an Elmiskop 1 and Zeiss *EM*9.

Fig. 1 is an electron micrograph of a section through an anaphase chromosome selected to show a special feature, namely, a long projection of chromosome material, 1–2μ in length, limited on either side by a lighter zone. Each zone consists of two membranes separated by a space and is essentially similar in structure to the nuclear envelope in interphase erythroblasts. The unusually light appearance of the space between the two membranes, and their low visibility, is mainly due to the high density of hæmoglobin. Although many sections through mitotic figures do not show such projections, they are not uncommon and have been seen in as many as five chromosomes per section; there were, at the most, two projections per chromosome. Membrane-limited projections have been encountered in cells at prometaphase, metaphase, anaphase, telophase and interphase. Examination of serial sections showed that such projections are in fact sections through sheets of membrane-limited chromosomal material. In one series a chromosome projection, 2μ long, persisted through seven silver sections, constituting a sheet 2μ by, at least, 0·5μ. Although the dimensions in the plane of the sheet are variable, the width of the chromatin sheets, at all stages, is approximately constant with an average value 464 ± 35 Å (mean of 74 measurements). The fine structure and staining properties of the sheets are similar to those of the main chromosome body, namely, fibrils and granules about 20–40 Å diameter.

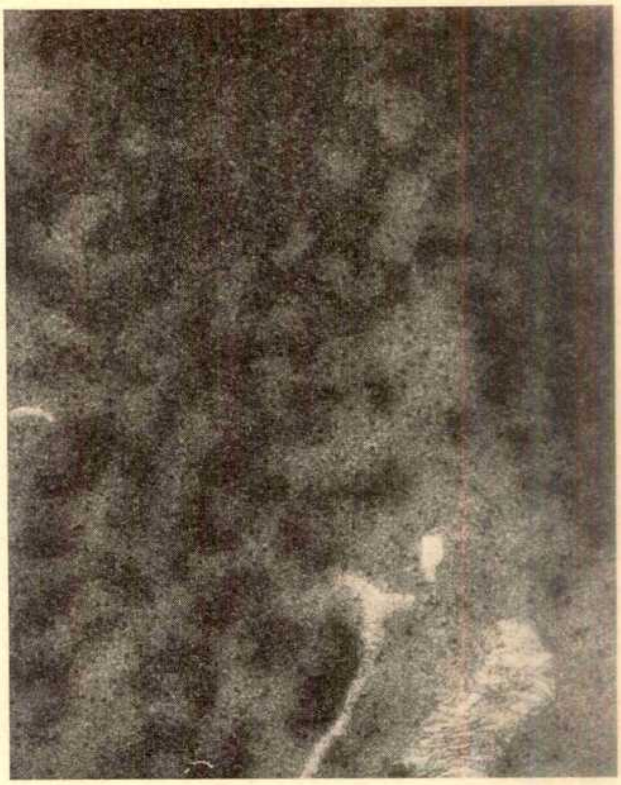

Fig. 2. Electron micrograph of part of an anaphase chromosome, one cut tangential to surface (× 30,000)

A second feature of these chromosomes is the irregularity of their surface, which is especially apparent when the section is cut tangential to the surface (Fig. 2). Although the surface structure has not yet been examined extensively, serial sections suggest that many of the irregularities correspond to relatively short (2000–6000 Å) projections, approximately cylindrical in shape, with a diameter of about 1000 Å. These projections are apparent from prometaphase onwards, until the stage of telophase clumping when they cannot be distinguished. Surface irregularities occur in mitotic chromosomes from both plant and animal species[11–14].

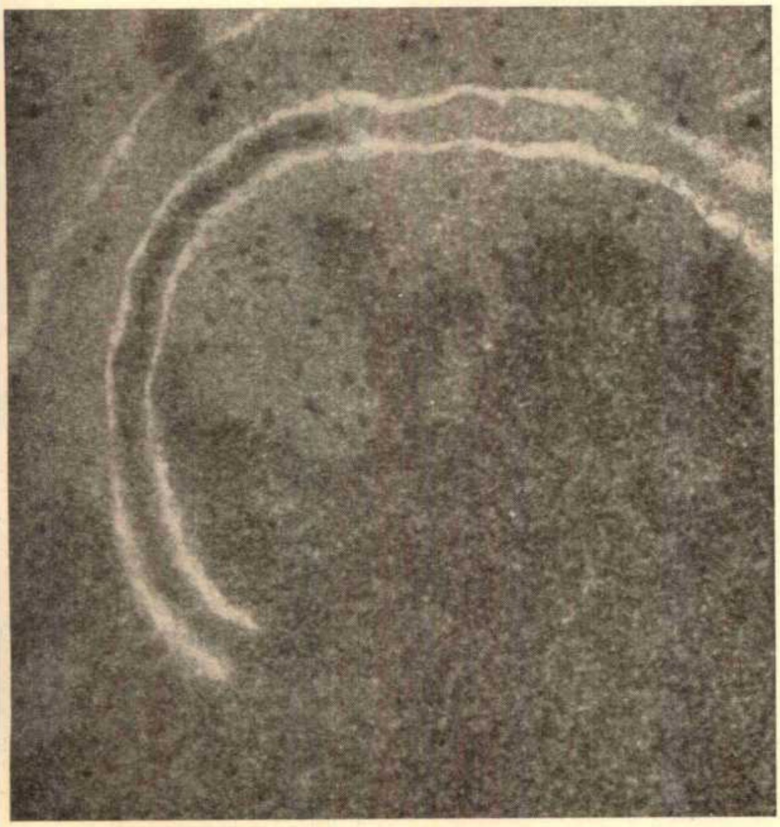

Fig. 1. Electron micrograph of part of an anaphase chromosome (× 80,000)

The most interesting aspect of our observations is the constant thickness of the membrane-limited sheets of chromosome material. Almost certainly the membranes are part of the nuclear envelope. Although the mode of origin and significance of the sheets are not yet established, the following suggestions are made. Although the constant thickness of the chromosome sheet may merely be the result of some peculiar transformation, and depend solely on the properties of the nuclear envelope, it is more likely that the width of the sheet depends on the properties of chromatin itself and is some aspect of a constructional unit, intermediate in size between DNA molecule and chromosome. We may suppose a sheet or sheets of chromatin, each 450 Å thick, to be actually present in the interphase nucleus. During the formation of the chromosome in prophase the sheet of chromatin, apposed to the envelope, remains stable under its influence and is not assembled into the main cylindrical body of the chromosome. During the motion of the chromosomes, a piece of free nuclear envelope becomes attached to the other side of the chromosomes sheet, resulting in a stable sheet complex. The occurrence of sheets in these chromosomes may be due to the high concentration of cytoplasmic hæmoglobin affecting the interaction of nuclear envelope with chromatin.

The surface topography of chromosomes appears to provide clues about their organization. For example, our data are consistent with a model in which the chromosome is formed by successive coiling of a thread 450 Å in diameter. In the interior of the chromosome these threads are packed so close together that their presence is not disclosed. However, at the surface, due to irregularities in coiling, the hypothetical 450 Å thread forms a loop, the elements of which twist round one another to form a projection about 1000 Å in diameter. Furthermore, a thread laid down on a surface may fold to form a sheet. Sheets may rise at the so-called clumping stage[15,16] of telophase when the chromosome is supposedly partially uncoiled into the 450 Å threads. New nuclear envelope associates with the chromosomes at about this stage and we assume that sheets so formed persist during interphase as heterochromatic regions attached to the nuclear envelope, only to appear in the subsequent division as the sheet structures we have figured. However, a model[8] formed out of coiled sheets cannot be excluded.

We thank Dr. J. H. Frenster for directing our attention to electron micrographs[17] of interphase nuclei in certain human neutrophils, which contain projections probably corresponding to sections through sheets of chromatin about 500 Å wide. We thank Miss Pamela Rush for her assistance.

VIROLOGY

Isolation of Louping Ill Virus from Small Mammals in Ayrshire, Scotland

THE natural history of louping ill, particularly the role of small mammals, has been little examined although the disease is still a major veterinary problem in many hill sheep-farms in Scotland. Findlay and Elton[1] showed that the short-tailed vole, *Microtus agrestis*, is susceptible to intracerebral inoculation with the virus. The occurrence of natural infections in wild animals such as red deer, *Cervus elaphus*[2]; red grouse, *Lagopus scoticus*[3]; and hares, *Lepus* sp.[4], suggested that the virus had a wider natural host range than sheep and cattle.

The rough pasture of coarse grass and rushes on many hill farms supports a large population of small mammals, particularly voles, shrews and wood mice. This is also the typical habitat of the tick, *Ixodes ricinus*, the arthropod host of louping ill. Most species of small mammals in such biotopes are infested with immature stages of *I. ricinus* and, in areas where louping ill occurs, they are exposed to the bite of infected ticks.

In March–April of 1962 and 1963, small mammals were collected from three farms around Dalmellington, Ayrshire, where louping ill is known to be enzootic, and wher investigations of the ecology of the disease in sheep are als being made[5]. The shrews, voles and wood mice wer caught in Longworth traps and the moles in Duffus traps The common shrew (*Sorex araneus*) made up 44 per cen of the collections, the short-tailed vole (*Microtus agresti* 27 per cent, and the wood mouse (*Apodemus sylvaticu* 13 per cent. The mole (*Talpa europea*), pygmy shre (*Sorex minutus*), bank vole (*Clethrionomys glareolu* and water shrew ((*Neomys fodiens*)—in that order— accounted for the rest of the collections (Table 1).

Table 1. ISOLATION OF LOUPING ILL VIRUS FROM BRAINS AND SPLEEN OF SMALL MAMMALS COLLECTED IN AYRSHIRE, SCOTLAND, IN 1962 AND 196

Species*	Total collected	Virus isolations from brains and spleens No. processed	No. positive	Infectio rate %
Mole (*Talpa europea*)	13	13	0	0
Pygmy shrew (*Sorex minutus*)	10	9	0	0
Common shrew (*Sorex araneus*)	100	68	1	1·5
Water shrew (*Neomys fodiens*)	6	3	0	0
Short-tailed vole (*Microtus agrestis*)	61	32	0	0
Bank vole (*Clethrionomys glareolus*)	8	6	0	0
Wood mouse (*Apodemus sylvaticus*)	30	26	2	7·7
Total	228	157	3	1·9

* Common names are those given in Southern (ref. 6)

After collection, the animals were lightly anæsthetize and examined for ectoparasites. Blood for antibody investigations was collected under anæsthesia from the cavernous sinus through the optic foramen. The animals were killed, and the brains and spleens removed, then sent on dry ice to London, where they were stored at −60° C until processed. In the 1962 investigation, the brain and spleen from each animal were ground up separately, each in 1·0 ml. of 0·75 per cent bovine albumin in borate saline buffered at pH 9. The suspensions were pooled, centrifuged and the supernatant inoculated intracerebrally into mice 2–3 days old, each mouse receiving 0·01 ml. The rest of the suspension was stored at −60° C in sealed ampoules. In the 1963 investigation, the brain and spleen from each animal were processed separately.

In 1962, virus was isolated twice: from the pooled brain and spleen of a wood mouse (*A* 596) collected on April 12 and from the pooled brain and spleen of a common shrew (*A* 603) collected on April 13. In 1963, virus was isolated only once: from the spleen of a wood mouse (*A* 743) collected on March 30. All three isolates were shown to be identical with louping ill virus, and they were successfully re-isolated from the original suspensions.

Table 1 shows the number of brains and spleens processed and the number of isolations. The overall infection rate in the small mammals was 1·9 per cent; the infection rate in the wood mouse was 7·7 per cent and in the common shrew 1·5 per cent.

There seems to be no doubt that some of the small mammals in louping ill areas become infected with the virus. This is supported by the finding of antibodies to the virus in their blood and the fact that they are infested with larvæ and nymphs of *I. ricinus*. However, to show whether these small mammals can maintain foci of infection in Nature in the absence of sheep, or whether they influence the frequency of infection in sheep, depends on further investigation of a number of factors: their population densities, their degree of tick infestation and the levels of viræmia which occur in them.

Larval infestation rates of small mammals appear to be lower in Britain than in Europe[7], where small mammals have been found naturally infected with Central European tick-borne encephalitis virus which is also transmitted by *I. ricinus*[8]. Moreover, the small mammals examined in Ayrshire are not maintenance hosts of adult *I. ricinus* and therefore could not themselves maintain a population of infected ticks.

Little is known about louping ill viræmia in small mammals. In one experiment, a wood mouse inoculated intraperitoneally with louping ill virus had viræmia on the first, second, third and fifth day after inoculation and survived to develop antibodies. The highest titre, 1·1 log mouse LD_{50} per 0·03 ml., was obtained on the third day. This may be below the threshold required to infect feeding larvæ. Small mammals such as shrews, voles and wood mice may be of particular importance in their peak population years when they probably act as amplifiers of the infection. They may do this in two ways: (1) The larger number of larval hosts present in these years probably substantially increases the proportion of larvæ which succeed in feeding and thus in surviving. (2) At the same time a proportion of the larvæ probably become infected. Together these will increase the risk of infection in sheep in subsequent years. A similar phenomenon has been shown to happen in Czechoslovakia, where outbreaks of tick-borne encephalitis in human beings have followed 'mouse years'[9].

We thank the late Mr. James Murdoch, and Mr. John Murdoch, for their unfailing hospitality and for permission to trap on the farms; Mr. J. M. Ferguson for advice on trapping, Messrs. J. Smart, R. Kinloch, J. C. Cunningham, R. J. C. Page, S. C. Srivastava and Miss Iva Albert for assistance with the trapping; Mr. A. L. Wilson of the West of Scotland Agricultural College for providing laboratory facilities at Auchincruive, Ayrshire; Dr. Chan Yow Cheong and Miss Margery Dorr for examining and dealing with the trapped animals, and the Agricultural Research Council for a grant towards the field expenses of this work.

PSYCHOLOGY

Sensitivity of Hands to Visible Light

Recently, reports have appeared in the press of experiments demonstrating the existence of a dermal sensitivity to intensities and wave-lengths of visible light. Many of the experiments do not appear to have precluded thermal effects. and B. Konstantinov has suggested[1] that the results may be explained by the perception of reflected infra-red radiation emitted by the hand. In the experiment recorded here these effects have been reduced, and college-age subjects have been required to discriminate between black and white.

In the experiment the subject placed one hand in a dark box, above two (2 in. × 4 in.), 1 in. deep, black chambers, one of which contained a white lint-covered plate and the other a black. The interchangeable plates were illuminated by an external fluorescent lamp, and were separated from the subject's hand by a 3-mm thick window of heat-absorbent glass (Chance *ON*20 which transmits less than 5 per cent of the incident infra-red). The intensity, above the window, of the light reflected from the white plate was 0·00012 lumens/cm², this being 3·5 times the intensity above the black.

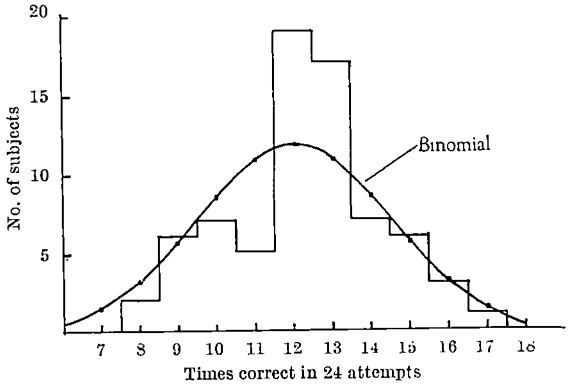

Fig. 1

The subject was given a few minutes in which to learn the difference between black and white before being tested 24 times. Before each test the plates were placed in the chambers on a pre-determined random basis by an experimenter invisible behind a screen. The subject was given no knowledge of her performance until the end.

The results for a total of 73 subjects (66 women) are shown in Fig. 1. No individual showed significance at the 5 per cent level. The results were combined and a significance level of 8 per cent was obtained ($\chi^2 = 14·4$, 8 *d.f.*)—reflecting a slight tendency for the subject to be right rather than wrong. A test merely for discrimination (curve folded) gave a significance level of 11 per cent ($\chi^2 = 7·6$, 4 *d.f.*).

At this relatively low light intensity the experiment does not appear to support the proposition that hands are sensitive to visible light.

We thank Mr. J. D. Valentine and Dr. M. J. Pickersgill for useful discussions.

Central Adaptation in Mechanisms of Form Vision

Perception of any visual pattern is subject to three well-known forms of adaptation. In the first place a 'negative after-image' is formed which tends to reduce the contrast between the brightnesses of neighbouring areas. Secondly, after more prolonged fixation, peripheral parts of the visual field tend to fade from view in large patches. With a stabilized retinal image, it is well known that a third type of adaptation can occur, in which the whole field fades and reappears intermittently.

With a randomly structured field such as an enlarged photograph of sandpaper (Fig. 1*a*) I have recently observed a fourth type of adaptation which seems to be distinct from all of those mentioned. After ten or twenty seconds' fixation, monocular or binocular, the clarity of one's visual image is unimpaired but the texture of the field assumes a curiously uniform character. The coarser features disappear and leave a mottled pattern reminiscent of a tufted carpet. Some observers report that the mottling has a roughly periodic character, the unit cell subtending an angle of the order of 1 degree. There is evidence also that the character of the uniform field seen is partly determined by the form of the region of the random field fixated. During monocular fixation a kind of rivalry is observed between the mottled image and a dark field, subjectively associated with the occluded eye, criss-crossed by a highly active population of randomly distributed dots and lines in motion.

The original pattern at once reappears, with enhanced vividness, if fixation is displaced by a few degrees. If the

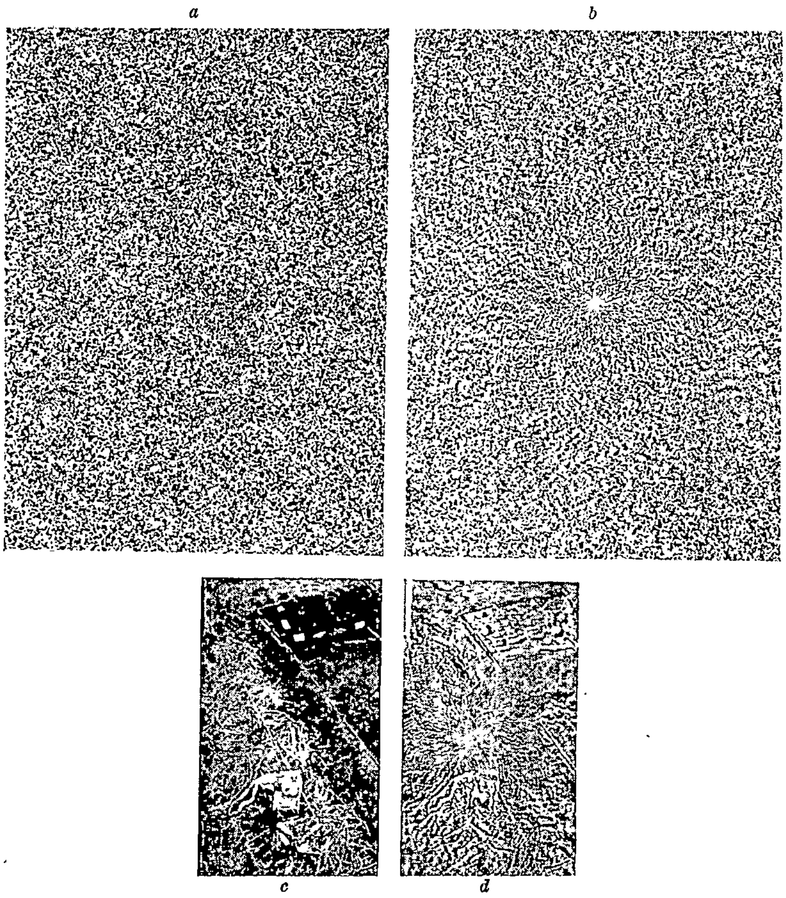

Fig. 1

originally fixated position is resumed within 1–2 sec, the uniformly mottled appearance returns, proving that the adaptations concerned are local to each area of the visual field stimulated. Though this might at first seem in some way to implicate local retinal adaptation to brightness, two further observations indicate that the phenomenon is different in origin. In the first place, the use of intermittent illumination, which partially overcomes brightness adaptation, does not restore the original form. Secondly, the same tendency towards homogeneity is found with the 'all-or-none' pattern of Fig. 2, in which simple brightness adaptation could affect only the contrast.

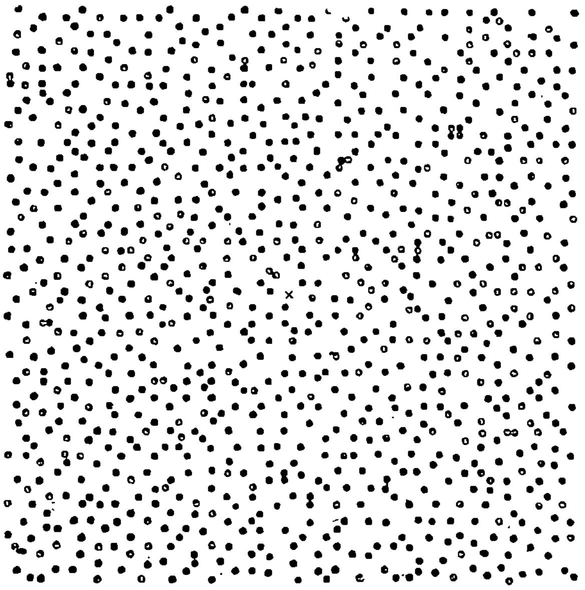

Fig. 2

It is tempting to interpret this phenomenon in terms of the contour-detecting and other form-sensitive neural mechanisms adumbrated by earlier observations[1] and reported recently in lower animals[2–4]. It would not be surprising if the long-range interactions between receptive fields required for the computation of form were more vulnerable to adaptation than those concerned with the signalling of brightness contrast, particularly when the redundancy of the pattern is low. The latter qualification is reinforced by the observation that with pages of newsprint, and other massive stimuli in which regular contours are present, such 'figural' adaptation is not observed to anything like the same extent.

The foregoing effects should be distinguished from another visual phenomenon observable on prolonged fixation of such random fields, namely, the transient appearance of spiral patterns. These seem to have a simpler explanation. As the reader can easily verify, they can be produced at will by suddenly rotating the fixation field by a degree or two. It seems reasonable, therefore, to attribute them to small torsional eye-movements.

It is not perhaps obvious at first sight why rotation in this case should generate spirals rather than circles. The reason becomes clear, I think, if one superimposes positive and negative photographic images of identical fields, such as Figs. 1*a* and *c*, with a slight relative rotation. The results are shown in Figs. 1*b* and *d*. Close to the centre of rotation, only edges which happen to lie radially are sufficiently displaced to be enhanced. At greater distances from the centre of rotation the optimal displacement for contour enhancement is exceeded for edges lying radially, but is achieved for those lying at progressively larger angles to the radius. The loci suggested by these enhanced contours thus tend to be spiral. Figs. 1*c* and *d* have been included to indicate that the effect is strengthened when the primary image is rich in long black or white edges at all angles. In the production of spirals observed when viewing a field such as Fig. 1*a*, the part of 'negative' is presumably played by the adapted retina.

Notwithstanding its irrelevance to the first phenomenon described, this mechanism of spiral-production may possibly be of interest in connexion with another type of central adaptation—the generation of spiral 'complementary images' when a field of random visual noise is viewed through or against a pattern of radial lines[1,5]. Since it is known that in this case eye movements are not responsible[6], the appearance of spirals raises the question whether lateral inhibitory action along the radial contours produces in effect a displaced 'negative' of the figure of neural excitation, which combines with the primary figure in analogous fashion to Figs. 1*b* and *d*.

FORTHCOMING EVENTS

Sunday, August 30—Wednesday, September 2

British Association for the Advancement of Science (at Southampton)—Continuation of 126th Annual Meeting.

Sunday, August 30

At 10.30 a.m.—Official Service in St. Mary's Church. Preacher: The Very Reverend the Dean of York, Canon Alan Richardson, M.A., D.D.

Monday, August 31

At 10 a.m.—Dr. W. Marshall: "The Exploration of Solids Using Thermal Neutrons" (Kelvin Lecture).

At 10 a.m.—Mr. W. H. Wilcockson: "Some Aspects of East African Vulcanology" (Presidential Address, Section C).

At 10 a.m.—Dr. C. A. Ralegh Radford: "History and Archæology" (Presidential Address, Section H).

At 11.30 a.m.—Prof. Lucy Mair: "How Small-scale Societies Change" (Presidential Address, Section N).

At 2.30 p.m.—Dr. H. A. Thomas: "Automation" (Young People's Lecture).

At 8 p.m.—Prof. A. S. Parkes: "Biological Aspects of the Population Explosion" (Evening Discourse).

Tuesday, September 1

At 2.30 p.m.—Dr. E. J. Ambrose: "Cells at Work" (Young People's Lecture).

Wednesday, September 2

At 10 a.m.—Dr. G. R. Coope: "Insect Populations in the Ice Age" (Darwin Lecture).

At 10 a.m.—Dr. V. B. Proudfoot: "Bringing Archæology to Life" (Lister Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer or Lecturer (preferably with experience in radiation or radioactive isotope measurements) in the Department of Biophysics, for activation analysis and trace element work—The Secretary, St. Thomas's Hospital Medical School, London, S.E.1 (September 5).

Research Engineer (with an honours degree in mechanical engineering and experience in the design or testing of engines) in the Department of Mechanical Engineering, to work on a project concerning the assessment of lightweight I.C. engines—The Registrar, The University, Sheffield (September 5).

Assistant Lecturer (with a degree in mathematics or the physical sciences and preferably some postgraduate experience) in Computing—The Registrar, University College of North Wales, Bangor, North Wales (September 7).

Lecturer in Pathology (Morbid Anatomy)—The Registrar, The University, Bristol, 8 (September 7).

Assistant Statisticians (2) (with a degree or diploma in technology in mathematics, or in pure or applied biology with "A" level in mathematics), for work on the planning and analysis of experiments—The Secretary, Glasshouse Crops Research Institute, Worthing Road, Rustington, Littlehampton, Sussex (September 8).

Demonstrator (graduate with qualifications in dairying and dairy microbiology) in Dairy Science—The Registrar, University College of Wales, Aberystwyth (September 12).

Horticultural Economist (graduate, preferably with research, teaching or advisory experience in horticultural economics) in the Department of Agricultural Economics—The Registrar, The University, Nottingham (September 12).

Laboratory Superintendent (with a degree or equivalent qualification, and substantial experience with the equipment and supervision of mechanical engineering laboratories) in the Department of Mechanical Engineering, for duties which will include the supervision of technical staff; supervision, maintenance and development of laboratories and apparatus; ordering and accounting of equipment and stores; and implementing safety regulations—The Registrar, The University, Sheffield (September 12).

Lecturer and an Assistant Lecturer (with special interests in pure or applied mathematics or numerical computation or mathematical statistics) in Mathematics at Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee, Scotland (September 12).

Senior Lecturer or Lecturer in the Department of Materia Medica and Therapeutics—The Secretary, The University, Aberdeen (September 12).

Graduate Research Assistant (with a good honours degree in a biological subject, and preferably experience in genetics or cytogenetics) in the Cytogenetics Group of the Pædiatric Research Unit, to work on a population survey on human autosomal abnormalities—The Secretary, Pædiatric Research Unit, Guy's Hospital Medical School, London Bridge, S.E.1 (September 14).

Lecturer (either botanist specializing in biochemistry or biochemist preferably with research interests in plant pathology; or botanist specializing in plant virology) in Botany—The Registrar, The University, Manchester, 13 (September 17).

Senior Lecturer in Psychology and a Senior Lecturer or Lecturer in Statistics at the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, September 18).

Assistant Lecturer or Demonstrator (with medical qualifications registrable in the United Kingdom) in Pathology—The Registrar, The University, Manchester, 13 (September 19).

Senior Lecturer in Medical Statistics in the Department of Public Health and Social Medicine—The Registrar, The University, Edinburgh (September 19).

Senior Lecturer or Lecturer (with medical qualifications registrable in the United Kingdom) in Pathology—The Registrar, The University, Manchester, 13 (September 19).

Lecturer (preferably with research interests in lipoproteins or cytochemistry) in Biochemistry at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 25).

Lecturer in Animal Production—The Secretary, Wye College (University of London), near Ashford, Kent (September 30).

Professor of Geography at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (September 30).

Professor in the Department of Agricultural Biology, University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (September 30).

Professor of Mathematics at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (September 30).

Research Assistant (preferably with an honours degree in zoology or medical sciences and a knowledge of German; persons graduating this year will be considered) to Prof. J. Z. Young in the Department of Anatomy, for work mainly on the central nervous system—The Secretary, University College, Gower Street, London, W.C.1 (September 30).

Research Fellow and a Senior Research Fellow in Social Anthropology and Sociology at the Institute of Advanced Studies, Australian National University—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Scientific Officer (with a good honours degree in a biological subject and preferably with research experience in microbiology) to study the soil-surface microflora, particularly nitrogen-fixing algae—The Secretary, Rothamsted Experimental Station, Harpenden, Hertfordshire (September 30).

Senior Lecturer in Psychiatry at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Senior Lecturer (with experience in any field of botanical science) in the Department of Botany, Monash University—The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia; or the Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 30).

Chair of Forestry at the Australian National University, Canberra—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 1).

Chair of Veterinary Clinical Studies at the University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, October 2).

Lecturer/Senior Lecturer in the School of Anatomy, The University of New South Wales—The Agent General for New South Wales, 56–57 Strand, London, W.C.2; and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (October 5).

Assistant Lecturer or Lecturer in Textiles and Clothing in the Department of Domestic Science, University College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (October 8).

Lecturer/Senior Lecturer in Animal Production in the Faculty of Agricultural Science, University of Tasmania—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 9).

Senior Lecturers (Clinical) (2) in Pathology, University of Queensland, Brisbane, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, October 16).

Assistant Director of Research (with a degree in agriculture or agricultural science or suitable postgraduate qualifications in these subjects, and substantial experience of the agriculture of developing countries) in Comparative Agriculture—The Secretary, School of Agriculture, the University, Downing Street, Cambridge (October 31).

Lecturer (with a university degree in chemical engineering, plus five years' approved industrial experience) in Chemical Engineering—The Director, The Swinburne Technical College, John Street, Hawthorn, E.2, Victoria, Australia (October 31).

Senior Fellow or Fellow (with several years' research experience in some branch of astronomy) on the Academic Staff of the Mount Stromlo Observatory—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Director, Mount Stromlo Observatory, Australian National University, Canberra, A.C.T., Australia (Australia and London, November 2).

Assistant Lecturer (graduate in science or engineering with a special interest in physical or physico-chemical properties of polymers) in Polymer Science in the Department of Materials—The Registrar, The College of Aeronautics, Cranfield, Bedford.

Experimental Officer (with basic scientific knowledge to at least G.C.E. "A" level or H.N.C., and preferably experience in electronic circuitry and high-vacuum methods with engineering design and drawing capability) for participation in researches in plasma spectroscopy, supported by U.K.A.E.A. (Culham)—Dr. W. R. S. Garton, Physics Department, Imperial College, London, S.W.7.

Lecturer in the Department of Organic Chemistry—The Registrar, The University, Liverpool, quoting Ref. CV/266.

Livestock Officer (with a degree in agriculture with animal husbandry or animal health as a major subject) in the Bahamas, to advise small farmers on methods of improving pastures and the quality of local sheep, goats and cattle, and to supervise co-operative livestock associations and pasture development schemes—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. No. RC 213/14/01.

Physicist (between 25 and 35, with a good science degree and preferably experience in research and experience of textiles), to take charge of investigations of fundamental importance to the hosiery industry—The Secretary, Hosiery and Allied Trades Research Association, Thorneywood, 7 Gregory Boulevard, Nottingham.

Post-Doctoral Research Fellow (with experience in adsorption studies or in mass spectrometry) for the spectroscopic investigation of molecules absorbed on surfaces—Prof. N. Sheppard, School of Chemical Sciences, University of East Anglia, Wilberforce Road, Norwich, NOR 77H.

Post-Doctoral Research Fellows (2) (physicists or engineers) for work on magnetic and optical properties of metals and non-metals—Dr. R. R. Birss, Physics Laboratory, University of Sussex, Brighton, Sussex.

Scientific Officer (with an honours degree or equivalent in engineering or physics) for investigation of behaviour of tractors and implements on sloping land, particularly effects of forces arising from slopes on motion of machines—The Secretary, National Institute of Agricultural Engineering, Scottish Station, Bush Estate, Penicuik, Midlothian, Scotland.

SENIOR RESEARCH ASSOCIATE IN THE SCHOOL OF CHEMISTRY for research into reaction mechanisms in boron chemistry—The Registrar, The University, Newcastle upon Tyne, 2.

TECHNICAL ASSISTANT (female, 20 or over, with advanced level G.C.E. in physics and mathematics, or the equivalent) IN THE PHYSICS DEPARTMENT, for duties concerned with the medical application of radioactive isotopes, and training will be given in the specialized techniques involved—The Secretary, The Royal Infirmary, Leicester.

Quickfit® leads the world with interchangeable laboratory glassware

From Manchester to Mandalay; from London Town to Leningrad, laboratories of every type are served by QUICKFIT glassware.

Once you take QUICKFIT products into your confidence you too will reflect on their distinct advantages— the sheer quality of the glass, the clever design, the precision ground connections and the remarkable finish.

Take a look at QUICKFIT — clearly it leads the world.

SCIENTIFIC AND INDUSTRIAL RESEARCH UNDER REVIEW

THE annual report of the Council for Scientific and Industrial Research for 1962 was discussed in these pages in the context of the report of the National Economic Development Council, *Conditions Favourable to Faster Growth* (*Nature*, 199, 207; 1963). That report, as well as the further report, *Growth of the United Kingdom Economy to 1966*, is now noted in the report of the Council for Scientific and Industrial Research for 1963*, as are also the reports both of the Trend Committee and of the Robbins Committee and further reports which have been issued by the Federation of British Industries on *Civil Research Policy* (*Nature*, 199, 725; 1963), and by Political and Economic Planning on the *Government's Role in Applying Science to Industry* (*Nature*, 200, 503; 1963). The Research Council does not comment on these reports, but its latest annual report reflects nothing of the near hysteria with which the Trend Report, for example, was received in some quarters.

Conscious that the future of the Department of Scientific and Industrial Research is under review, the Research Council has chosen instead to make a dignified and considered statement setting forth what it considers as a set of guiding principles which it has evolved over the past seven years. These it regards as sufficiently flexible to meet any demands which may be made on the Council, and the statement records also the progress of the Council's thinking so far, in the light not only of the experience of the Executive Council but also of almost half a century of achievements by the Department. Moreover, the account of activities is better balanced than that given in some of the Council's annual reports and appropriately attests the soundness of the Council's claim that, throughout its seven years' existence, it has been at pains to emphasize the responsibility of the Department across the whole spectrum of research and development from basic science to industrial application and the dangers inherent in any arbitrary division of this responsibility.

The tendency detected in one or two of the Council's reports to arrogate responsibility that properly belongs to the Advisory Council on Scientific Policy is absent from this report, nor is it dogmatic as to the relations with the National Research Development Corporation or the National Economic Development Council. It is admitted that flexible means should be found, as experience develops, of harnessing public and private means for research and development to support established national requirements and priorities. There is no further evidence as to the effectiveness of the research associations or any inherent weaknesses in the conception, but here also there is a reasonable and a flexible outlook. The whole statement is not only dignified but also reflects a confidence arising from conscious strength and proved achievement that cannot be disregarded; it is a distinctive contribution to impartial decision as to the future of the Department and its relations with other bodies.

The statement suggests that a main task of the Government is to secure that the right proportion of resources is put into the conduct of research and its application by British industry, and that these resources are distributed as wisely as possible between the various branches of science and technology, and between the main types of activity—basic research, applied research, development and information and advisory services. The Trend Committee was, of course, charged with the responsibility of advising how far existing arrangements were appropriate for that purpose, and its recommendations are intended to provide a more efficient and effective structure, capable of meeting an increasing competition for scarce resources. Since the Research Council was first established as an executive body, expenditure on scientific and technological research and development in Britain has doubled from about £350 million in 1956–57 to about £700 million in 1962–63. However, the gross expenditure of the Department of Scientific and Industrial Research has increased from just more than £8·25 million to nearly £19·5 million. Although in earlier days the separate activities of the Department in encouraging academic and industrial research, and conducting research in the national interest, were separately planned, and control was kept to the minimum to ensure public funds were not wasted, closer attention to the selection and control of research programmes is now essential.

Recently, the Research Council has come to the conclusion that there are some shortcomings in the traditional pattern of control which could only be remedied if the Government took greater initiative. While these shortcomings are not precisely identified in the report, the Council states that it found that this task of considering the implications of such wider responsibility in a democratic society and finding effective tools for its discharge involved, first, identifying areas where the scale or pace of work is inadequate; secondly, discovering the reasons and suggesting possible ways of dealing with them; and thirdly, ensuring appropriate action. Within the orbit of the Council's own responsibilities, important parts of the first two of these tasks have been entrusted to its standing Economics Committee, which reviews industries to discover where research and development are lacking, and its Research Grants Committee, which is directing special attention to important research fields where increased effort and better co-ordination of existing effort may be desirable. The Council's statement is mainly concerned with the outcome so far of these enquiries.

First, while techniques for surveying requirements, industry by industry, are still being worked out, the Council is satisfied that surveys by economists and technologists afford a promising method: the findings can make a noticeable impact on key people in the industries concerned, and a careful follow-up of the recommendations can secure a larger and more balanced effort in research and development in which teaching and research institutions and industrial firms can all play their part. Clearly this activity is related to the activities of the National Economic Development Council, and the Research Council is now considering what help the Department could give to the economic development committees being set up by the National Economic Development Council for particular industries. This aspect, which is particularly concerned with faster economic growth and economic performance, may well assume greater importance in view of the evidence that, over the first five months of 1964, industrial output has ceased to grow.

The Economics Committee is also attempting to establish sound economic criteria for national priorities in research and development. The Research Council reports that it is too early to say how successful this attempt may be, but in the absence of any details it would seem that such investigations are more appropriately made directly for the Advisory Council on Scientific Policy. This Committee has also been considering the national need for research and postgraduate investigations in applied economics. The Research Council's own experience indicates that available knowledge of the workings of the industrial economy is insufficient to provide a sure guide to policy. Difficulties have also been encountered in recruiting appropriately trained and experienced economists for work under the Committee, and the Council has transmitted its conclusions on the urgent need for more support for research and training in economics to Lord Heyworth's Committee on Social Studies.

As regards research in universities and colleges, the Research Council records a disappointing response to the indication that it would welcome applications for research grants within those areas indicated by a survey made in 1960 for the Advisory Council on Scientific Policy, which identified or confirmed important gaps in biology, technology and some subjects on the fringe of two or more disciplines. It is clear that some expansion of research is needed in some branches of technology and biology, and the Council has modified its procedures where necessary to assist this purpose. Here it is assisted by a series of sub-committees, which review applications and make recommendations to the Research Grants Committee, and three of these sub-committees—technology, metallurgy and metals, and biology—are conducting reviews, sometimes with the help of special panels, to stimulate more research in areas where it is especially timely and promising. The technology sub-committee has now been divided into two panels, and a new sub-committee has been set up for computer science.

Maintenance of the balance in research effort implies reconsideration of the level of support for work in established areas, particularly work requiring large teams or expensive equipment. Here the Research Council is particularly concerned with nuclear physics, which still absorbs about a quarter of the money available for its research grants. This it does quite apart from expenditure by universities and colleges out of general funds and the large sums going to the National Institute for Research in Nuclear Science and the European Organization for Nuclear Research. Since important advances can only be made with large and very expensive equipment and a single project may need a large part of available resources, the establishment of priorities in nuclear research has become important. The Research Council states that it will not feel justified in assigning further large sums to nuclear physics unless it is first assured that its support for other branches of science and technology is adequate.

It might be observed that the Secretary of State for Education and Science, or the Advisory Council on Scientific Policy, seem better placed and more appropriate for such decisions. However, clearly the problem is one that the Council for Scientific and Industrial Research cannot escape, any more than it can escape involvement in some problems of policy to which it next directs attention. With expensive apparatus or large research teams, ensuring that the work is done in the most suitable place and in the most effective way may involve a choice between new or existing locations and cannot always be divorced from the personality of the professor directing it. Should such a professor move elsewhere, the Research Council must clearly satisfy itself that his successor is able and willing to develop the work successfully. Here and in other ways it may be difficult for the Research Council to avoid trespassing on academic autonomy, but the Research Council is manifestly anxious to face and solve such problems in close collaboration with the universities themselves.

In determining changes necessary in the Department's duties to achieve a balance of effort in its work for Government and industry, the Council has directed special attention to its research stations, the research associations and civil research and development contracts with industry. In the whole field the Department's present main responsibilities are: to undertake scientific research to advise Government departments, local authorities and other public bodies in the exercise of their responsibilities; to provide industry with basic scientific and technological data and standards of measurement; to be the vehicle for Governmental financial support for industrial research and development in the Department's own stations and in industry; and to further the dissemination of the results of researches and their practical application. As regards the Department's own stations, the Council expresses satisfaction with the results of the experiment with small compact steering committees in place of the large advisory boards, and considers that there is much to be said for small closely-knit groups when trying to keep research programmes flexible in the face of changing needs. This is contrary to the view of the Zuckerman Committee, which did not think that such steering committees should be a normal feature in running a research establishment. Nevertheless, the Research Council is convinced that independent review committees can be useful in taking a wider look at the scientific and technological needs against the background of university and industrial resources and the developing needs of the community. Such a committee is looking at the functions of the Water Pollution Research Laboratory.

On the research associations, the statement records that the scheme has again been examined to ensure that the policy of support is rational and that the research associations themselves—to the expenditure of which (more than £9 million a year) the Government contributes some £2 million—are as vigorous as possible. The Council regards the traditional pattern of grant for associations which have passed their first stage of growth as inadequate. While there is now no suggestion that these associations are being forced to grow faster than their industries wish, the new grant policy still involves progressive stiffening of terms but in relation to the industrial circumstances of each association. Apart from seeing the associations develop their service to industry to the full and encouraging them to undertake sponsored work, the Council has now offered a new form of support in earmarked grants enabling them to undertake work for which they are best fitted, which is important in the national or long-term industrial interest, but which is unlikely to receive the necessary support or priority. The first of such grants was to the British Welding Research Association in upport of fatigue investigations of welded construcion.

On research and development contracts the Council omments that its policy has been to confine support to rojects representing a major technical advance and or which another department is not already responsible. t recognizes that inevitably only a small proportion f those submitted would be accepted, but it is disappointed that so few contracts have yet been placed. Accordingly, it is seeking to bring together the industrial users, the manufacturers of machinery and equipment, and scientists working in related fields, for example machine tools and printers' machinery, to specify projects which are likely to be technically feasible and commercially desirable. Again, a thorough survey has been made of the field of superconducting materials and as a result proposals are now being considered for research both in universities and in industrial laboratories in the three main directions in which intensified effort is needed: fundamental research into the properties of thin films and the mechanism of operation of superconductors; the production of materials; and the construction and operation of superconducting magnets.

Little is said in this section of the report about relations with the National Research Development Corporation. In spite of the evidence of the competence of the present Council for Scientific and Industrial Research, there are wider considerations not touched on in, or within, the scope of this report to which regard should be had before a final decision is taken on the relations between the Council and the Corporation, or whether the latter should be placed within the Board of Trade, or be responsible to the Secretary of State for Education and Science. This present report should ensure that the achievements and the limitations of the Council for Scientific and Industrial Research are fairly assessed when decisions are taken as to the future organization of civil research; however, the report by no means disposes of the arguments of the Trend Report.

One other matter calls for comment. This year the Council gives a little more space to its activities and responsibilities in the field of technical information, where it considers a transformation is needed in the traditional means of encouraging the adoption of new ideas by industry. Nevertheless, there is only the briefest account of the National Lending Library for Science and Technology, now making loans at the rate of 5,500 a week, and making a survey of the use made of its resources and an examination of the resources of the 2,000 organizations (more than half of them industrial concerns) to which it lends. The Council admits that the problem of communicating to small firms that have no technical expertise is still largely unsolved, and that an efficient network of information centres requires far more resources than can be obtained from local industrial contributions. It has now assisted the Scottish Education Department to foster a scheme whereby the four central technical institutions in Scotland and the Royal College of Science and Technology, Glasgow (now the University of Strathclyde), appoint out of their general funds officers of senior lecturer rank whose main responsibility is industrial liaison in the surrounding area.

So much interest has been aroused by this innovation that the Council has made arrangements with the Ministry of Education under which existing regional technical information centres in England will be brought into the scheme during the next three years. The Council does not regard this step as offering a final solution to the problem, but it is of interest in indicating that the Council now realizes the importance of measures on a national scale if the library and information needs of Britain as a whole are to be served effectively. The same outlook can be seen in the new arrangements for the grant to the Association of Special Libraries and Information Bureaux (Aslib), under which the Council will be responsible for virtually the full cost, up to an annual limit of £20,000, of a programme of research into documentation problems of national interest, beginning with investigations on information storage and retrieval. This research grant is intended to enable Aslib to concentrate more of its resources on longer-range investigations and to build up a strong research team, and is independent of a second grant to the Association for other activities. The Council also concurs in the view of the Advisory Council on Scientific Policy as to the serious neglect of documentation research in Britain. It would be reassuring as well as welcome if both Councils showed a keener awareness of the way in which the various aspects of library development and information services are interlocked in Britain. Moreover, it would be pleasing to find that they were fully alive to the significance of the work of the Committee on Libraries appointed by the University Grants Committee and the Ministry of Education, of the early development of the new National Reference Library for Science and Invention, and of the development of the public libraries under the Public Libraries and Museums Act which received Royal Assent on July 31.

FINANCING MEDICAL RESEARCH

THE Office of Health Economics was founded in 1962 by the Association of the British Pharmaceutical Industry to undertake research to evaluate the economic aspects of medical care, investigate from time to time other health and social problems, collect data on experience in other countries, and publish relevant results, data and conclusions. The Office has now issued a paper* which puts the expenditure on medical research in the United Kingdom in 1961–62 at about £24 million, with a further £3 million for providing new buildings for research. More than half this came from Government funds, one-third represents the research expenditure of the pharmaceutical industry in Britain—about £7·8 million, compared with £2·8 million in 1953—and the balance is made up by medical research charities and trusts, such as the British Empire Cancer Campaign or the Wellcome Trust. Medical research accounts for about 4 per cent of the total expenditure on research and development in the United Kingdom; about 3·5 per cent of both Government and industrial research expenditure is devoted to medical ends.

There was a rapid increase in expenditure on medical research in Britain in the 'fifties, that of the Medical

---

* *The Finance of Medical Research.* Pp. 32. (London: Office of Health Economics, 1964.) 2*s*.

Research Council and of the pharmaceutical industry increasing more than three-fold, and expenditure by trusts and foundations probably even more rapidly. Expenditure by the Medical Research Council expanded faster than the expenditure on the National Health Service, and that of the pharmaceutical industry rose much more rapidly than the industry's total sales or sales to the health services. The rate of expansion in research expenditure by the Government and by industry appears to be slackening since the early 1960's. Half the medical research charities in Britain were founded or reconstituted during the 1950's, and the trend appears to be continuing. Eight charities were responsible for £1·8 million of the total expenditure on medical research from private sources of just more than £2·3 million in 1962 (there was a further £1·6 million for buildings)—a figure which does not include direct donations from the public to universities or other medical research units—and, of this, £1·2 million came from the British Empire Cancer Campaign. Both the Imperial Cancer Research Fund and the National Fund for Research into Poliomyelitis contributed £400,000, and although the expenditure on research by the remaining charities is small, it increased from £128,000 in 1961 to £208,000 in 1962. The Mental Health Research Fund also increased its expenditure on research, in spite of a fall in income.

The distinguishing feature of these charities is that they approach medical research in terms of diseases rather than along disciplinarian lines such as endocrinology or pathology as in the universities, or by the pharmacological investigation of chemical substances as in the pharmaceutical industry. This varied approach gives them an important place in medical research and, although the magnitude of their contribution is not great in specific fields, its marginal effect can be significant. The paper instances research into multiple sclerosis, where, although voluntary societies have supported only 1 per cent of the effort, this 1 per cent has permitted a few research workers to work intensively and draw together the research effort in this field.

Of the major trusts concerning themselves with the medical field, namely, the Wellcome Trust, the Nuffield Foundation, the Nuffield Provincial Hospitals Trust, the Leverhulme Trust and the Wolfson Foundation, the latter two tend to concentrate on providing buildings for general medical research purposes, rather than financing the conduct of research. However, it is worth noting that almost half the £2 million allocated by the Wellcome Trust in 1960–62 was for new buildings for established departments with research reputations, and £450,000 of the £647,000 allocated by the Nuffield Foundation in 1961–62 was for buildings. Both the trusts and the charities have a crucial advantage over Government agencies in the flexibility of their support, both in form and in direction, and the paper suggests that the volume of private benefaction in the United States may have been an important factor in the lead established there in medical research.

Medical research expenditure in the United States for 1961 is estimated at about £370 million, and at the beginning of the 1960's it amounted to 3·6 per cent of the expenditure on health, compared with an expenditure in Britain on medical research of 2·7 per cent of the costs of the National Health Service. A total expenditure on medical research in 1961 of £35 million, instead of the £27 million, would have been needed to reach the ratio of medical research expenditure to all health expenditure prevailing in the United States, and, to match the pace of expansion in that country, this would need to rise to £5 million by 1963. Furthermore, the expenditure on medica research in the United States in 1963 was almost half the total cost of the National Health Service, but the paper points out that, whereas the latter places the main emphasis on satisfying present-day needs, in the United States the Government's responsibility for the health of the community is discharged primarily through research aimed at long-term improvement.

Precise comparisons of national expenditure on research are difficult and can be misleading, and probably the value of this survey lies rather in its analysis of the structure of the finance of medical research and its assessment of the several factors that determine not simply the scale but the objectives of research. The mere fact that the pharmaceutical industry in the United States spends some £81 million on research, or ten times the amount spent by British industry, has little meaning apart from such further analysis. The share of support between Government and industry is very similar in both countries: the most important difference in the sources of support is the larger proportion coming from charities and trusts in the United States—13·8 per cent compared with 9·7 per cent in Britain. Furthermore, since the beginning of the 1960's, the Federal Government has been increasing expenditure on medical research at almost twice the rate of increase of Government expenditure for this purpose in Britain.

This is particularly relevant in considering the expenditure on medical research of the pharmaceutical industry itself, and in noting the tendency for such expenditure by British industry to slow down its rate of expansion in the 1960's. It is also noted that this has been attributed to the greater economic risks which the industry faces as a result of the erosion of patents and the general discouragement of the prescribing of branded products, from which the pharmaceutical firms undertaking medical research draw much of their revenue. The section which discusses the economic problems of industrial research is one of the most useful in the paper, for it brings out the issues involved in the general question of research and economic growth and the weakness of the patent protection which the products of medical research really enjoy. Scientific knowledge, research and innovation have yet to find a place in the framework of economic analysis, and the economic model of a firm based on marginal costs and returns has little relevance in understanding the problems and growth of science-based industry.

The present pharmaceutical industry is principally a creation of research, but research is not a direct cost of production: it is an overhead cost, and marginal analysis tends to ignore the implications of overhead expenditure. The paper explains clearly the difficulties that arise in considering the impact and place of research, and particularly the nature of research overheads, which have been consistently ignored in recent debates in the House of Commons when the supply of drugs to the National Health Service has been under consideration. Little appreciation was then shown of the greater risks of losing the advantages that the patent system was intended to afford in support of research and which the holder of a patent originating from pharmaceutical research faces through his greater liability to compulsory licence.

Here again the paper brings to the forefront the real problem. It is true that the magnitude of the financial support for medical and allied research is a key factor in determining the speed of medical progress, but the financial backing is by no means the only factor. Moreover, while inadequate support may limit the rate of advance, an increase in funds does not necessarily lead to an acceleration. The intractable character of some problems may mean that advance depends on progress in other fields, not obviously related, and even so, new understanding makes no impact on health until it is translated into new medical procedures.

The paper does well to point out that under the National Health Service there is now no danger that the public will be deprived for economic reasons of the benefits of medical research, a danger which the safeguard of compulsory licensing in the patent system was originally intended to avert. There is, on the contrary, the question how far the system now affords sufficiently effective protection to ensure a flourishing and progressive pharmaceutical industry in Britain, but behind this lie the more fundamental questions asked in this paper: how much should be spent by the Health Service on medical goods, and where does the balance of public advantage lie? Does it lie in stimulating medical research or in obtaining short-term economies in National Health Service expenditure?

These questions dig at the very roots of the issues concerned with the relations between the research-based industries supplying medical goods and the Health Service. Public accountability for expenditure has tended to emphasize the Government's present responsibility at the expense of the long-term commitments with which the Federal Government is primarily concerned in the United States. Moreover, appraising the economics of these industries in traditional terms, with excessive emphasis on costs of production, and failing to take into account the relation between research and production, only aggravates the problem. Nor does it help to ignore the implications of the use of trade-marks or brand names by industrial firms to protect their discoveries. To the inventor these also are part of the means of financing further research, and some 95 per cent of branded medicines prescribed under the National Health Service are manufactured by companies undertaking major research programmes. While some of these products are not the results of present-day research, all carry a share of its cost.

There is no simple way to judge whether Britain's present expenditure of some £27 million on medical research is either too low or too high or approximately right. There can be no objective standard for the right level for expenditure on medical research. This arises from the nature of research. What should be remembered is that the progress of medical science is a dominant factor affecting expenditure on the National Health Service, but the motive force of this progress is not economic. Where research is financed through revenue from the Health Services, the search for economies can impede research. In recent years finance for medical research which does not come from sales to the National Health Service has risen faster than that which does.

The conflict between the claims of present-day responsibility for health expenditure and long-term responsibility for the health of the community was implicit in the discussions in Parliament over the costs of drugs. Here it is brought out explicitly, with the warning, too, that depression of one sector of medical research may lead to false economies. When the question of the costs of medical care predominates, there may be a strong argument for encouraging lines of research which combine lower costs with more effective care, and the paper instances, as a promising field, lines of investigation making feasible domiciliary rather than hospital treatment.

The final assessment of the level and direction of medical research must depend on the broad issues of health and welfare of the community, not on narrow economic considerations. The level, moreover, may be adequate, but the allocation of resources may be poor, and this is at present tied closely to the system of financial support. We should be asking whether the right opportunities are being taken, whether funds at present spent on cancer or poliomyelitis research might return greater benefit if directed to the field of mental health, and again, whether if so much research is pursued along the lines of medical disciplines there may not be excessive concentration on the therapeutic rather than the preventive aspects of medicine. The paper does not pretend to give the answers to the searching questions which it asks, but it puts the whole problem of medical research into a perspective which should facilitate realistic and reasonable discussion.

FIBRE STRUCTURE

Fibre Structure

Edited by Dr. J. W. S. Hearle and Prof. R. H. Peters. Pp. xxv + 667. (Manchester: The Textile Institute: London: Butterworth and Co. (Publishers), Ltd., 1963.) 126*s*.

FOR the fifteen years since it was first published, Preston's *Fibre Science* has been a standard text in university courses in textiles. In recent years, however, its usefulness has been diminished by progress in the development of new fibres and in the understanding of old ones. The time is ripe, therefore, for a replacement, and this book on *Fibre Structure* is designed to that end. The general scheme of the new volume is similar to that of the old (it comprises a number of separate contributions which are, in fact, based on lectures delivered in a course at Manchester in 1959), but in one important respect there is a change. *Fibre Science* was aimed at the ordinary undergraduate or non-specialist; to a large degree it retained the philosophy of Astbury's *Fundamentals of Fibre Structure* that the basic sciences, as well as their special application to fibres, were unfamiliar to the reader. This volume is, in general, more sophisticated, and should appeal rather to honours students or postgraduates.

The title phrase is taken to cover not only molecular and fine structure but also grosser features of morphology and external characteristics, and the book is thus divided into three sections dealing with texture on three different levels. The first section opens with a discussion by Sharples of chain configuration in cellulose solutions and the possible chemical inhomogeneity of cellulose. In connexion with this latter topic I noted one of the few instances of discrepancies between different contributors, for Sharples can accept no more than about 1 per cent of non-glucose sugar in cellulose hydrolysates, whereas Preston, in a subsequent chapter, cites one source of what he defines as cellulose which contains as much xylose as glucose. The other chapters in this section deal with synthetic polypeptides and proteins (Bamford and Elliott), with nothing new but giving a good review, particularly of the chemistry and physics of the polypeptides; and with synthetic fibre-forming polymers (Goodman) and tactic polymers (Gordon), two chapters which I thought exceptionally good. My only adverse criticism of this section on molecular structure, and I hope that this is not tendentious, is that it would have been nicely rounded off by a chapter on wool chemistry. Certainly those (there are still a few of us) who regard the study of wool as something of a cult will agree that in this one respect *Fibre Science* surpasses its successor.

The second section of the book is, perhaps, the most important, since it deals with topics which are more controversial. It starts with an introductory chapter (Hearle) of a historical character, which surveys the development of micellar/fibrillar hypotheses and describes the author's own fringed fibril concept. A feature of this chapter is the attention directed to the ideas of Kargin and his school; but, in trying to be fair, Hearle has been too objective in his treatment, quoting extensive extracts from the Russian papers without criticism. In particular, to offer to students without comment the notorious fragment "Electron microscope investigation of cellulose and its ethers reveals that they are amorphous and that the entire electron diffraction pattern is determined by the ordered arrangement of atoms in the molecule of cellulose and this gives evidence of the absence of strict order in the mutual distribution of their molecules" is distinctly unwise. In my opinion, the apparent unorthodoxy of Kargin's views arises largely out of a lack of agreement as to the proper definition of such terms as "crystalline", "amorphous", and "oriented".

The chapters on fine structure in plant fibres (Preston) and animal and man-made fibres (Sikorski) emphasize the part which electron microscopy plays in structural investigations nowadays; since both emanate from Leeds it would be improper for me to do more than mention their scope. Preston's contribution is largely based on his own work on algae and wood tracheids, and Sikorski's does something to redress the comparative neglect of keratin in previous chapters. Treloar (the non-crystalline state) and Keller (crystallinity) have complementary topics. Treloar deals somewhat briefly with mechanical properties, with a good introduction to transition phenomena. Keller gives a very readable account of a fascinating field of study only marred by a teasing tendency to stop a discussion with the apology that space does not permit more. He is, of course, chiefly concerned with crystallization from the melt or from solution, where the evidence for folded chains is now conclusive; the phenomenon of fibrillation in drawn fibres he regards as one which illustrates the inadequacy of our knowledge of fibres at present, an opinion which is echoed by Thompson in a later chapter when he notes that ". . . the final fibre structures are very similar whether crystallization occurs first at spinning or is delayed until drawing".

The remainder of the book deals with grosser structural characteristics, surface and fibre morphology, skin and core effects, and other properties which are important in end-product use or in the technology of fibre manufacture. It also includes, as a welcome luxury, chapters on glass (Jellyman) and asbestos (Whittaker) fibres.

There is no doubt that *Fibre Structure* will exert a very considerable influence on the teaching of fibre science at the higher levels for a long time, and the standards of topic and presentation are such that this influence will be mostly for the good. It is a pity, therefore, that the editorial introductory chapter should fall below the general level of excellence; it is here that I noted the few examples of inadequate proof reading (dicarboxylic acids $HO(CH_2)_n$ COOH on p. 5, wrong formulæ III (p. 6) and VI (p. 8); and if II (p. 6) is not wrong it seems particularly inapt for student consumption). There are also one or two examples of factual error, particularly in references to keratin; but perhaps more disturbing, since we often grumble about the standard of student English, is the number of inelegances in the editorial English, of which one example will suffice: "The disposition of the cells varies with the fibre and may be peripheral, as in mohair, or composed only of one kind". Having just finished marking degree scripts, I am in no mood to stomach this sort of thing in a text-book! H. J. WOODS

BRYOPHYTE BIOLOGY

The Structure and Life of Bryophytes

By E. V. Watson. Pp. 192. (London: Hutchinson and Co. (Publishers), Ltd., 1964.) 15*s*. net.

THE writing of a small book on a very large subject is not an enviable task; it is a task, however, which Dr. E. V. Watson has fulfilled and fulfilled admirably. In spite of the fact that this is one of the "University Library" series, it may be recommended whole-heartedly to other than university students—a tribute in itself in days when 'student' and 'university student' are often thought of as synonymous, and books so tailor-made for syllabuses as to deter the 'amateur' who learns for the pleasure of learning, and whose existence is frequently ignored. Dr. Watson obviously enjoys his subject, and thus writes enjoyably. Abundant references for those who wish to take any point further are skilfully interpolated without losing the thread of a discussion or the flow of reading matter.

The title of the book gives a true idea of its contents, and every aspect of bryophyte biology is dealt with. Taxonomy, physiology, ecology . . . all disciplines are given their rightful, equal place, and Dr. Watson takes a thoroughly balanced view. As with most modern biological investigations, the phylogenetic aspect is stressed, though some might consider the opening sentence of the concluding chapter—"The gross morphology of a bryophyte is chiefly of interest in an evolutionary context"—to be going a bit far. Few will quarrel with the statement that the clue to phylogeny is to be found in the aberrant (taxonomic entities); rather might this be extended to the downright teratological. It is good to see (p. 87) natural relationships stressed against technical characters even of the sporophyte. Too often natural genera have been split on such characters (*Tortula*, *Polytrichum*). On the other hand, through lack of them, even the family of a well-known species, for example the plant known as *Trichostomum sinuosum*, may remain somewhat in doubt.

It may be noted (apropos of the differences between *Calobryum* and *Haplomitrium*, p. 45) that Berrie (*Proceedings of the Linnean Society of New South Wales*, 87) has already aired Schuster's conclusion that the distinctions between these two genera are invalid. *Orthotrichum* does not always have the peristome teeth reflexed (p. 86). Of the mosses with 'amphigastria', the Rhacopilaceae simulate hepatics rather more than the Hypopterygiaceae. I myself feel that the number of bryophytes found in the tropics and temperate zones of both hemispheres will be higher than that of flowering plants as the monographic revisions so much desired by Dr. Watson and all bryologists are accomplished (p. 156). Unfortunately, since "bryophytes are unlikely to achieve great economic importance" (p. 175), these revisions are likely to remain as pathetically small as the number of full-time bryo-taxonomists. . . . Practically cosmopolitan species are not confined to the 'weedy species'. *Campylopus introflexus*, for example, has a tremendous area. The occurrence of the otherwise Australasian genus *Echinodium* in Macaronesia (p. 158) looks even more remarkable when we credit the area with *Gollania* (mainly far eastern) and *Tetrastichium* (South American affinities). Among the adaptations to xerophytic conditions, mention might have been made of strongly contorted leaves in the dry state, exposing chiefly the multistratose nerve to the influence of the atmosphere (for example, *Tortella nitida*, *Timmiella* spp.). The selection of material for the ecological section must have caused as much heart-searching as for that on geography, but it is a pity that mention could not have been made of Tutin's remarkable photographs of zonation of epiphyllous liverworts in the article by Richards in the *Manual of Bryology*.

These, however, are some of a legion of thoughts arising from Dr. Watson's book rather than criticisms. No doubt all its deservedly many readers will be similarly stimulated, and many postgraduate research workers will be grateful for the fruitful leads which the author supplies.

WHAT IS COMPARATIVE ENDOCRINOLOGY?

Comparative Endocrinology

Vol. 2. Edited by U. S. von Euler and H. Heller. Part 1: Invertebrate Hormones. Part 2: Tissue Hormones. Pp. xiii + 282. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963.) 86s.

IN reviewing Volume 1 of *Comparative Endocrinology* (*Nature*, 201, 120; 1964) I emphasized the exciting phase into which the subject has now entered, but pointed out that it has not, in Britain, yet gained that recognition which is its favoured lot throughout the world. However, this comment does not apply to insect endocrinology which, largely due to Sir Vincent Wigglesworth, has been a recognized and dynamic field for three decades or more. It was the more surprising and disappointing to find that Part 1 of Volume 2, "Invertebrate Hormones", occupies only some 62 pages.

In the first section, L. I. Gilbert considers "Hormones Controlling Reproduction and Molting in Invertebrates". He deals mainly with arthropods and particularly with the insects. Crustacea are cursorily dismissed in five pages. In the part on insect metamorphosis, the Holometabolous insects are emphasized to the almost complete exclusion of the Hemimetabola. The text arouses the curiosity, but by lack of information fails to satisfy it. For example, ". . . thorough study of the subspiracular glands in the Cecropia silkworm during all stages of development and obtained evidence of secretion at several critical stages". The nature of the studies is not described, nor are the critical stages given. The addendum is very scrappy and incomplete and should not, in any event, occur in this type of treatise. As a whole, instead of being a critical synthesis of the present state of knowledge, this part is a collection of selected findings from which the reader will have difficulty in discerning any emergent pattern. The second part, which includes insects and is a description of gross structure of neurosecretory systems by F. G. W. Knowles, is too short and superficial to be of any real value.

Part 2 comprises a miscellaneous collection of articles, including those on kinins, heparin, lipid anions, 5-hydroxytryptamine, cholinergic and adrenergic neurohormones and histamine. Whether all these varied compounds should be classed as endocrine is in doubt and certainly not enough is known to justify their presence in "Comparative Endocrinology". It is the strength of the comparative approach that a variety of animals, especially those below the sub-class Eutheria, can be considered. By so doing, light is thrown on fundamental processes of wide applicability, in animals wherein there is greater ease of access and fewer complicating factors.

A rag-bag of so-called 'tissue hormones', knowledge of which stems almost completely from a few mammalian laboratory animals, certainly makes no contribution to 'comparative endocrinology'. The articles might be considered useful if they urge comparative physiologists to look further. If this were the rationale of the editors it would have been justified if they had been included in Volume 1. As it is, Volume 2 serves comparative endocrinology ill in being neither particularly comparative nor unequivocably about hormones.

I. CHESTER JONES

NUCLEAR PHYSICS

Progress in Nuclear Physics

Vol. 9. Edited by Prof. O. R. Frisch. Pp. v + 310. (London and New York: Pergamon Press, 1964.) 90s. net.

THIS ninth volume deals with a variety of detection methods and with theoretical and experimental investigations, mostly, but not wholly, in the field of high-energy physics. Though research, in most of the matters considered, is still moving fast, a great deal of data exist, and the present book provides valuable information on the subjects considered.

The first two articles are devoted to electronic methods of particle detection, namely, "Spark Chambers" by J. G. Rutherglen, and "Semiconductor Counters" by G. Dearnaley. In the former the mechanism of spark production is fully discussed. A short description of some of the essentials of spark chamber operational techniques follows, and a number of valuable references are given for those wishing to set up complete systems. Of particular interest is the account given of the effects of clearance field on spark alignment, and of the assessment of track accuracy. In the second article the essential characteristics of the depletion layers of semi-conducting counters are outlined. The relative merits of this type of counter are well exemplified, in particular the energy measurement of short-range, slowly moving and heavily ionizing particles. Some of the disadvantages are also referred to, such as the very high noise background, experienced in fast rise time work, and the methods of combating this by fast–slow coincidence methods.

Then there is an article on "Theoretical Techniques of High Energy Beam Design" by N. M. King. It is often difficult to have at one's disposal a physical account of the principles of beam design, since beam design manuals often list only the computational parameters. This article provides such a physical description admirably. Details are given of the trajectories and phase space parameters of the particle beams for quadrupole and main bending magnets, and of fringe field effects. The properties and difficulties of electrostatic separators are outlined.

The "Introduction to the Structure Analysis of Collision Amplitudes" by R. J. Eden deals with the development of dispersion theory and the relation of its singularities to perturbation theory. Starting with derivations from causality, it leads to a discussion of the analyticity properties which hold in collision problems. Some of these sections may not be found easy, as the author himself seems to fear, but there are many references available. Two important interaction problems are helpfully mapped out and provide some of the underlying steps of a full analysis. The role of Regge poles in asymptotic behaviour is briefly indicated.

This is followed by a detailed 100-page article on "The Interaction of Strange Particles with Nuclei" by E. H. S. Burhop, D. H. Davis and J. Zakrzewski. A valuable introductory account is given on the interactions of kaons and hyperons with nucleons, and on mesic capture. The generalizations made to nuclei provide data on neutron reactions and, of particular interest, on those yielding Y particles among the final states. But in the presence of the other nucleons, other processes such as internal absorption can intervene, and these are detailed. Hyperfragments are discussed separately and a useful short analysis is given of Λ-nucleon binding forces.

Finally, there is the article on "Electromagnetic Properties of the Muon" by F. J. M. Farley. It is a very comprehensive and exciting story of recent electromagnetic measurements leading to definite specifications of the spin, mass and, particularly, the magnetic properties of this particle, and raising throughout the intriguing question of muon-electron differences.

Throughout the book there are abundant references, though these end mainly in 1962. The print is of good size, and the book is a pleasure to read.

G. M. LEWIS

PROGRESS IN NUCLEIC ACID RESEARCH

Progress in Nucleic Acid Research
Edited by J. N. Davidson and Waldo E. Cohn. Vol. 1. Pp. xiv + 424. 93*s*. Vol. 2. Pp. xiv + 346. 88*s*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963.)

THE rapid advance of biochemistry has been accompanied by an increase in both the number and size of journals; if one had to read every paper written in the field, there would be no time left for research work. This is especially true of the central field of nucleic acids; the scientific literature in this field has been growing exponentially since 1947 with a doubling time of about two-and-a-half years. As a result of this rapid growth, specialization has increased greatly, and there is a real danger that the fragmentation of the field will hamper scientific advance. There is, therefore, a great need for publications in which specialists can summarize and critically assess new developments, and this is precisely the main aim of the editors of *Progress in Nucleic Acid Research*. Volume 1 contains eleven articles which cover a large range of subjects. F. J. Bollum discusses the role of primer in DNA polymerase reactions. He draws a careful distinction between two kinds of 'primer'. The first, shown by oligodeoxyribonucleotides for calf thymus polymerase, leads to chain extension; in this case the primer is incorporated into the product and acts as an initiator in a linear condensation polymerization. The second type of priming is the better-known one; here the DNA primer is used as a template and guides the structure of the replica. It is, however, still not clear whether the polymerases extracted from cells are indeed the enzymes which act in DNA replication in the cell. In the case of the *E. coli* polymerase of Kornberg, the polymerization proceeds in only one chemical direction, whereas we know that in the cell both chains of DNA are copied together in one direction. It is conceivable that the polymerases may be enzymes used to repair DNA in the cell and the real replication enzymes remain to be discovered. The fact that many polymerases have an absolute requirement for denatured DNA as a primer may reflect their repair function, and Bollum discusses the difficulties involved in constructing models of replication based on the enzyme experiments.

Two articles deal with RNA synthesis. R. M. S. Smellie gives a useful general review of the subject, and directs attention to a group of enzymes with very curious and as yet unexplained functions. For example, there is an enzyme which is responsible for the incorporation of UMP residues alone, and there are other enzymes which can form homopolymers of adenylic acid. The second article by Hurwitz and August discusses the biochemistry of the DNA primed-RNA polymerase, the enzyme which is responsible for the transcription of DNA into RNA. This article contains an excellent summary of the careful experiments done by Hurwitz and his collaborators. M. Grunberg-Manago writes on polynucleotide phosphorylase. This is a most valuable article, since it collects in one place all the essential findings about this enzyme.

The paper on messenger RNA by F. Lipmann reviews the background of this subject and also discusses the interaction of messenger RNA with ribosomes, and the possible mechanisms of protein synthesis. The details of this process are still not clearly understood.

The review of the coding problem by F. H. C. Crick is a clear analysis of the status of work in this field, and discusses both the genetic studies and the experiments using synthetic polynucleotides. It becomes clear that the genetic code may be cracked, but it is not yet broken, and much further rigorous work will have to be done to provide the definitive codon dictionary.

Bendich and Rosenkranz present "Some Thoughts on the Double-Stranded Model of Deoxyribonucleic Acid"; their main theme is that all is not yet solved. They suggest that DNA structures other than the classical Watson–Crick structure may occur in cells and they direct attention to the possibility that DNA molecules may be linked by amino-acids or small peptides. These ideas run against the main trends in this field, and the evidence on which they are based will have to be very carefully evaluated. They claim that in some viruses and spermatozoa the volume occupied by the DNA, if it were exclusively in the doubled-stranded form, is larger than the volume available. The table illustrating this contention on p. 226 contains much misleading information particularly in the cases of $T2$ and $S13$.

There are three articles on the structure and physical chemistry of nucleic acids. Marmur, Rownd and Schildkraut have written an excellent review of "Denaturation and Renaturation of DNA"; Spirin reviews the structure of RNA and Luzzati writes on the structure of DNA as determined by small angle X-ray scattering. Finally, A. Wacker reviews the work on molecular mechanisms of radiation effects.

The editors have set a high standard in this first volume of the series. They are to be commended for the international character of the book. Above all, they must be congratulated on their powers of persuasion: everybody knows how difficult it is to elicit review articles from busy investigators.

Volume 2 maintains the standards set by the editors in the first volume. It contains a very important article on chemical mutagenesis by D. R. Krieg. We now know that there are major difficulties in trying to identify the nucleotide changes at induced mutational sites. The degeneracy of the genetic code and the possibility that many amino-acid changes will not produce defective proteins make the genetic analysis almost intractable. In addition, we just do not know all the chemical changes produced by mutagens in DNA, and in many cases there is no justification for assuming that the major chemical reaction has anything to do with mutation induction. Kreig's article is very clear and balanced and includes an analysis of all the mutants of the $T4$ r_{II} genes.

The article by Cavalieri and Rosenberg challenges the importance of Watson–Crick base pairing in guiding nucleic acid copying. They propose an alternative scheme in which specificity in copying is given by stacking interactions between bases rather than by hydrogen bonding. The article is speculative.

H. Harris's article centres around the question of the stability of messenger RNA. Must unstable RNA always be called messenger RNA and must messenger RNA always be unstable? Harris emphasizes that there is a nuclear RNA in animal cells which appears to be unstable but does not appear to be transferred into the cytoplasm.

R. Markham writes on plant virus nucleic acids, and he critically reviews the role of the RNA as a messenger, and the reports claiming synthesis of infectious tobacco mosaic virus RNA.

The other articles in the volume deal with chromatography of oligo- and poly-nucleotides (Stahelin), the mechanism of action of aza-pyrimidines (Skoda), *s*RNA (Brown) and an analysis of the mechanism of RNase (Witsel).

S. BRENNER

Encyclopedia of Chemical Technology

By Kirk-Othmer. Vol. 3: B to Calcium. Second, completely revised edition. Pp. xvi + 927. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1964.) 338*s*.

FOR an encyclopædia of chemical technology to be useful to the chemist and chemical engineer in industry, university or in a research organization, it must be as near perfection as possible. To achieve this perfection can be no easy task, since over the past decade, chemical technology has expanded to unbelievable levels. The editors of "Kirk-Othmer", supported by a large team of expert authors and reviewers, are to be congratulated on providing a compendium of information of chemical technology that is as near to perfection as possible, up to the time of printing. Every article, expertly written, contains a mass of information of industrial methods, materials, processes, equipment and, where possible, information on storage, transport, health and safety aspects. In certain cases details are given of new industrial research processes that are both in operation and at the experimental stage.

The third volume of the revised *Encyclopedia of Chemical Technology* covers 43 articles ranging from "Bacterial Infections" to "Calcium Alloys". The subjects reviewed follow closely those chosen in the first edition. In general, new articles cover materials which over the past decade have become of increasing industrial importance. For example, there is an article on "Bentonite", a clay that displays strong colloidal properties, and which is put to a multiplicity of uses in the pesticide, paint, abrasive, detergent and food industries. Also included are "Optical Brighteners", an article that summarizes the various types of fluorescent organic chemicals that are of utmost importance to the manufacturers of detergents, plastics and textiles. The omission of a selection of trade names in this article is to be regretted. In the analytical field, there is a good review on "Bioassays", where special reference is given to underlying theories and calculations.

It is disappointing to note the omission of the collective article on "Building Materials", a subject that is of world-wide importance. Although no cross-references are given, one must assume that this omission will be partially remedied by the inclusion in later volumes of separate articles on individual materials. K. FIELD

Local Rings

By Masayoshi Nagata. (Interscience Tracts in Pure and Applied Mathematics, No. 13.) Pp. xiii + 234. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1962.) 83*s*.

THIS book presents an up-to-date account of a flourishing branch of abstract algebra, to which the author has made notable contributions. It is No. 13 in the series of *Interscience Tracts in Pure and Applied Mathematics*. After an introductory chapter on "General Commutative Rings" there are chapters on "Completions and on Multiplicities", followed by a chapter on the "Theory of Syzygies". The latter is a new theory, taking the place of homological methods. As a result, homological algebra is not used in the book and the author claims that his theory is simpler than that based on homology theory. Later chapters cover the theory of complete local rings, geometric local rings and Henselian rings and Weierstrass rings. In an appendix, there is a valuable historical account of many of the important results in the text; there is also a comprehensive bibliography.

The exposition is somewhat condensed, although it is systematic, and it is assumed that the reader is already familiar with a good deal of the necessary background, in abstract algebra. The book is, in fact, for the specialist, but since it is virtually the only account of the subject it will be indispensable to every mathematician doing research on the theory of local rings. It is perhaps a little disappointing that the book does not reveal more of the geometric motivation behind the subject, and the algebraist who wishes to link up with this will have to study independently the subject of algebraic geometry. L. S. GODDARD

Aspens

Phoenix Trees of the Great Lakes Region. By Prof. Samuel A. Graham, Robert P. Harrison and Casey E. Westell, jun. Pp. xiii + 272. (Ann Arbor: University of Michigan Press; London: The Cresset Press, Ltd., 1963.) 7.50 dollars; 50*s*. net.

THIS book is devoted entirely to the two aspens that occur in the Great Lake Region of North America, that is, the trembling aspen (*Populus tremuloides*) and the bigtooth aspen (*Populus grandidentata*), so named because of its deeply indented leaves. The trembling aspen is a very common and widely distributed tree in North America, where it reaches 100 ft. It is transcontinental in its range and occurs from northern Mexico or California to the frozen tundra of Alaska. It is the only Californian tree to do so. The bigtooth aspen is less widely distributed, occurring from Maine and southern Canada to Tennessee and North Carolina. These two trees are of great importance in the forest ecology of some parts of North America and it is pleasing to note that they have received such close attention and study. Would that other trees in other parts of the world that are important constituents of the native forests could receive similar attention.

Both these species have been cultivated in other countries, including the British Isles, where they have not shown great promise or grown as well as other North American species of *Populus*.

In this work, the two trees have been studied from all angles, with the main emphasis on their ecology. Pests, diseases, sylviculture and utilization—all figure prominently. In recent years the trees have become of more and more importance as sources of paper pulp. Some of the work of postgraduate students, who have worked on specific problems concerned with aspens, is incorporated in the book and is acknowledged, as is financial assistance gratefully received from the forest industry of Lower Michigan. F. N. HOWES

Vegetative Anatomy of Plants

By H. G. Burström and Camilla Odhnoff. Pp. 148. (Stockholm: Svenska Bokförlaget, 1964.) n.p.

IT is no mean achievement to write a good introduction to plant anatomy in a book of only 148 pages. It is true that the authors' task has been made easier by the omission of any reference to floral anatomy, but, even so, they have succeeded in presenting the essentials of the subject very effectively. The language is simple, technical terms are not needlessly numerous and the meaning of each is clearly defined wherever it is first presented. The book is clearly and adequately illustrated. The text is based on a course of lectures given as part of the curriculum for a Swedish M.Sc. degree. The authors' special hope is that it will give an adequate introduction to plant structure to those botanists whose interests are mainly in plant physiology. The subject is covered in four main sections dealing respectively with the plant cell, the forms of cells and their mode of origin, the histological differentiation (ontogeny) of the plant body and ecological anatomy. There is a selected bibliography of 240 titles and an index.

Although the brevity of the book inevitably imposes limitations on its content, it is an admirable text for the type of readers for whom it is intended. It is to be hoped that the spelling will be more carefully checked in future editions. C. R. METCALFE

LIFETIMES OF GEOMAGNETICALLY TRAPPED ELECTRONS OF SEVERAL MeV ENERGY

By JAMES A. VAN ALLEN

Department of Physics and Astronomy, State University of Iowa, Iowa City

THE loss of charged particles from trapped orbits in the magnetosphere is a complex physical process, which is not characterized by any simple law. Hence it is not possible, in the strict sense, to define a single parameter which characterizes their lifetime. Nevertheless, there is now a large body of observational knowledge of the monotonic decrease with time of the intensities of trapped particles following a natural or artificial injection of such particles. The most definitive knowledge on the loss of energetic electrons comes from investigations of the time history of nine artificial radiation belts which have been produced by U.S. and U.S.S.R. high-altitude nuclear explosions in 1958 and 1962. In Fig. 1 is shown a sample set of curves of intensity versus time for the fission-decay electrons from the *Starfish* nuclear explosion of July 9, 1962, as observed with satellites *Injun* I and III. The counting rate is that of a small, heavily shielded Geiger tube (designated *SpB*) which detects the trapped electrons via their intermediate bremsstrahlung in the shield. The response of the *SpB* detector[1] is due primarily to electrons the energies of which lie in the range 1·5–5 MeV. The curves of Fig. 1 are for a particular value, 1·25, of the McIlwain magnetic shell parameter L and for a succession of values of the scalar magnetic field B within that shell. It is clear that there is a relatively rapid decrease of intensity within the first $\sim 1{,}000$ h after injection and that this transient period is followed by a much longer one characterized by an approximately constant slope on a semi-logarithmic plot. It is noteworthy that the value of this slope is independent of B.

For $L \lesssim 1·25$, an essentially complete theoretical understanding of the time-decay history of the *Starfish* radiation belt has been achieved by Walt[2] in terms of scattering and energy loss in the atmosphere.

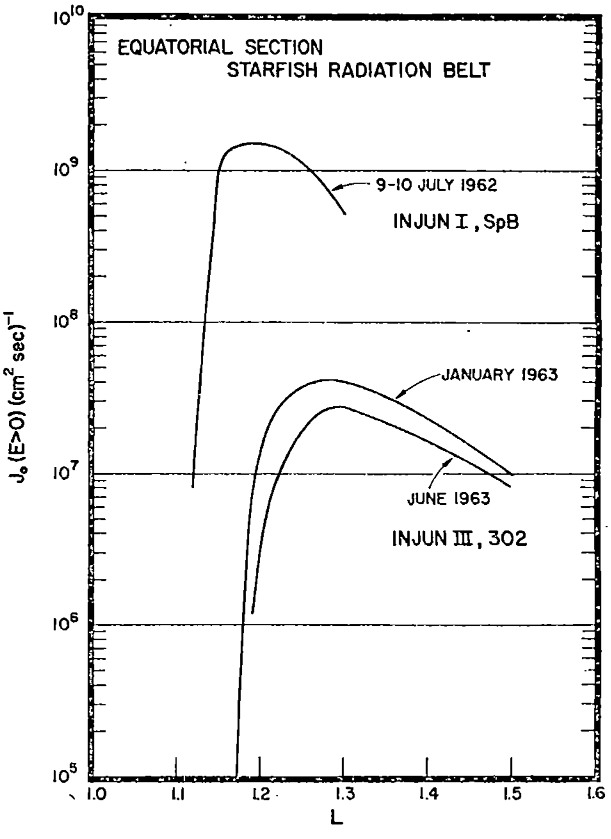

Fig. 2. An abridged summary of the time-history of the *Starfish* radiation belt. The ordinates are in absolute units

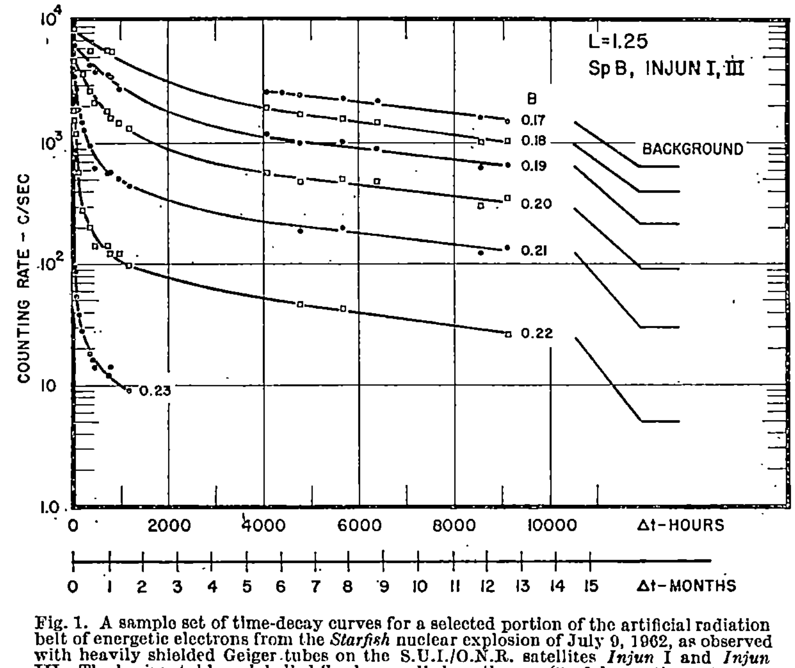

Fig. 1. A sample set of time-decay curves for a selected portion of the artificial radiation belt of energetic electrons from the *Starfish* nuclear explosion of July 9, 1962, as observed with heavily shielded Geiger-tubes on the S.U.I./O.N.R. satellites *Injun* I and *Injun* III. The horizontal bars labelled 'background' show the pre-*Starfish* counting rates corresponding to the several members of the family of curves. Δt is the elapsed time after the detonation

For the purposes of this article the L-dependent quantity τ in $\exp(-\Delta t/\tau)$ is termed the 'apparent mean lifetime' of ~ 2-MeV electrons during the main decay-phase, that is, for $\Delta t > 1{,}000$ h (Fig. 1).

The overall decay of the *Starfish* radiation belt is shown in Fig. 2.

An example of the decay of the intensity of energetic electrons in the composite radiation belt produced by two Soviet nuclear detonations on October 22 and 28, 1962, is shown in the lower panel of Fig. 3, taken from *Explorer* XIV observations by Frank, Van Allen and Hills[3].

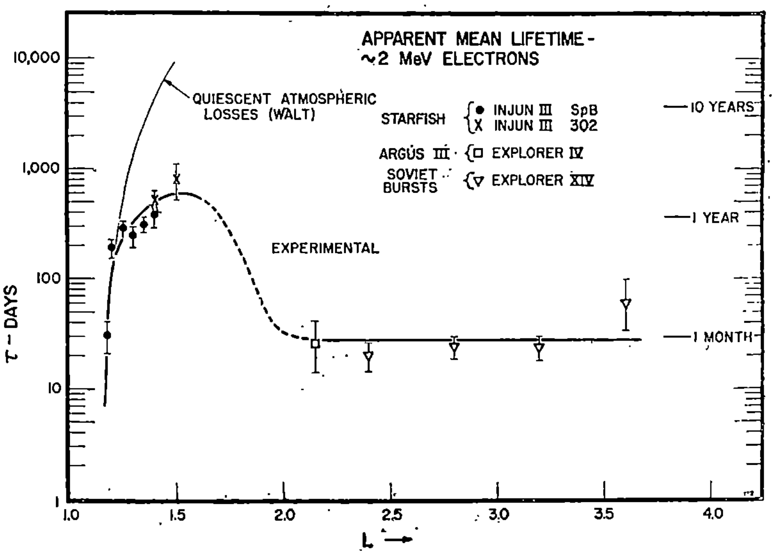

Fig. 4. The L-dependence of observed values of the 'apparent mean lifetime' of ~ 2-MeV electrons from two U.S. and two U.S.S.R. nuclear detonations at high altitudes. Note that the theory of quiescent atmospheric losses is adequate for $L < 1·25$ but departs heroically from the experimental curve for $L > 1·25$ (see text)

Fig. 4 gives a summary of the L-dependence of experimental values of the apparent mean lifetime of ~2-MeV electrons. The general nature of this dependence has been known for some years[4] from investigations of the time variations of the intensity of energetic electrons in the natural radiation belts. For $L \lesssim 1·25$, the loss of electrons is dominated by 'quiescent' scattering and energy-loss processes in the outer atmosphere. For greater L values such processes become of relatively trivial importance and the loss of particles is dominated, presumably, by electromagnetic and magnetic processes in the geomagnetic field as it is subjected to perturbations by terrestrial sources (for example, whistlers, and other very-low-frequency phenomena) and by erratic buffeting by the solar wind at its outer boundary. The observed lifetime of ~2-MeV electrons has a maximum value of about 2 years at $L = 1·5$, then declines rapidly to values of the order of one month for L from 2·0 to 3·5. Examination of time variations in the population of energetic electrons of similar energy in the natural radiation belts[3,5] shows that, even during periods of relatively low solar and geomagnetic activity, the effective lifetime declines at greater L to values of the order of a few days at $L \sim 8$. Beyond $L \sim$ 8–10, durable trapping is not possible. Fragmentary investigations in the region of the 'slot' between the inner and outer radiation belts ($L \sim 1·8$) have shown that there are large, sporadic time variations there. This fact suggests that the effective value of τ may fall considerably below the dashed portion of the experimental curve of Fig. 4 in the range $1·6 < L < 2·1$.

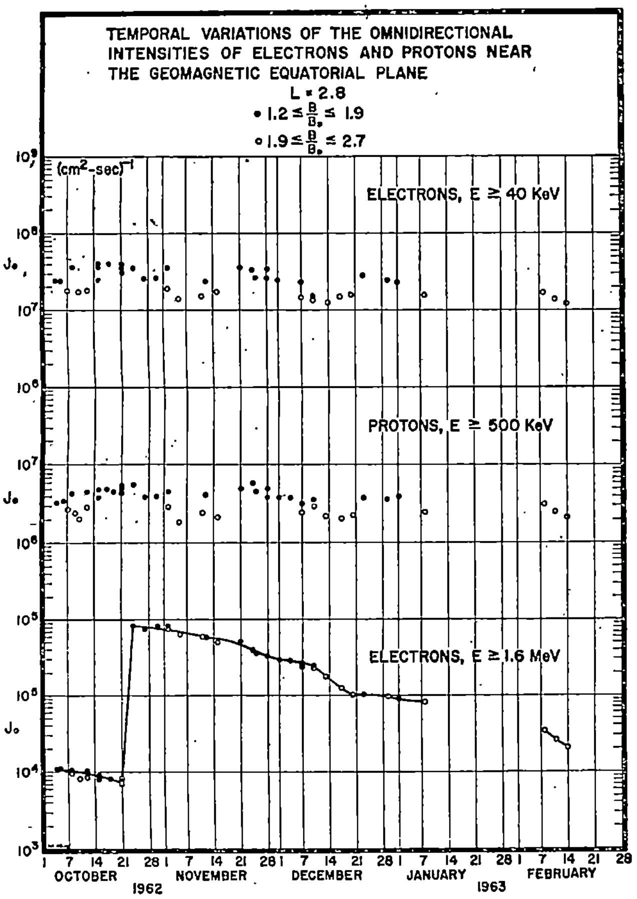

Fig. 3. In the lower panel is shown the time-decay of the intensity of energetic electrons from the U.S.S.R. nuclear detonations of October 22 and 28, 1962. Note, in the upper two panels, the negligible effect on the intensities of electrons of energy greater than 40 keV and of protons of energy greater than 500 keV (ref. 3)

Finally, it is noted that there is no established theory of the loss of trapped particles for $L \gtrsim 1·25$. The observational evidence suggests that the time-history of the intensity of electrons at the greater L values consists of a sporadic sequence of discontinuous perturbations, some of which result in the loss of particles and some of which result in replenishment[4,5]. The overall tendency is for specifically injected electrons to lose their identity and to be assimilated into the general mêlée. Hence, effective values of τ for $L \gtrsim 1·25$ are almost certainly dependent on the general level of solar activity and on the consequent level of geomagnetic activity, τ being expected to be less during periods of high solar activity. An incidental aspect of this line of thought is the tentative 'explanation' of the outer boundary of the inner-zone-distribution of energetic protons ($E \gtrsim 20$ MeV) which has been suggested previously[1,4].

I thank the U.S. Office of Naval Research (contract *Nonr* 1509(06)) for its support and Drs. W. C. Lin and L. A. Frank for their assistance.

INFLUENCE OF THE SATELLITE *Io* ON JUPITER'S DECAMETRIC EMISSION

By E. K. BIGG*

C.S.I.R.O. Radiophysics Laboratory, Sydney, Australia

A CONSIDERABLE amount of experimental and theoretical work has been performed on the bursts of radio emission emanating from Jupiter at frequencies of about 20 Mc/s since this radiation was discovered by Burke and Franklin[1]. It was realized by Shain[2] that the signals tended to recur at fixed intervals which could be associated with Jupiter's rotation. Subsequent work has fixed this period with considerable precision, and a co-ordinate system, known as System III longitudes, based on it, is now in use. The emission is thought to be associated with the motion of electrons in Jupiter's vicinity, the enhanced probability of radiation when particular parts of the planet face the Earth being due to the orientation of the planet's magnetic field.

Jupiter has four large satellites, of which the closest, I*o*, has a mass and distance from Jupiter almost identical with the mass of the Moon and its distance from the Earth. Since the Moon exerts at least some control on the Earth's magnetic field through the electrons in or beyond the ionosphere, it is reasonable to ask if I*o* influences the signals coming from Jupiter.

I thank Dr. James W. Warwick, who has made available to me his four-year catalogue of Jupiter events before its publication. In this catalogue is recorded the U.T. start and finish of each event, its frequency range, intensity on a scale of 1, 2 or 3, character and frequency drifts. In 1960 there were only 52 events recorded, but in 1961, 1962 and 1963 there were 240, 334 and 380, respectively. The last three years contain sufficient material for analysis by separate years and have therefore been exclusively considered.

To find whether Io has any effect on the emission, the following procedure was adopted. Time zero was taken as a moment, known as superior geocentric conjunction, when Io crossed the Earth–Jupiter line on the far side of Jupiter, and is given in the *American Ephemeris and Nautical Almanac* of the appropriate year. Each Jupiter event was then recorded in terms of elapsed time from the last zero. A table of 2,550 columns was then constructed (one for each minute of Io's period as seen from the Earth) and, for each minute during which a signal was observed, an entry 1, 2 or 3 corresponding to signal intensity was made in the appropriate column. The columns were then summed in consecutive groups of 10, the last group being adjusted for the fact that Io's mean period is only 2,548·5 min. The procedure gives more weight to the more intense events, but similar results are obtained if one considers only the frequency of occurrence.

The results for the individual years are shown in Fig. 1, and for three years combined in Fig. 2. While there are some differences between the years, there is a remarkably close correlation, particularly with the positions of the two largest peaks.

I*o* therefore appears to control the decametric emission which reaches the Earth to a surprisingly large degree. It is of theoretical importance to know whether the position of the satellite with respect to the Earth–Jupiter line or the Sun–Jupiter line is the more relevant. Seen from Jupiter the Earth's orbit subtends an angle of more than ± 11°, so that if the Sun–Jupiter line were used to

First Paperback Edition of
Six Famous Textbooks
LECTURES ON THEORETICAL PHYSICS

By Arnold

Sommerfeld

From the student's point of view, the great attraction of Sommerfeld's lectures lies in their clarity—the approach from the physical side, the formulation of the mathematical problem, and the simple and general explanation of the mathematical terms used.

Six volumes—EACH priced at 31s.

Volume 1, 289 pp.

Mechanics

Review : "For anyone interested in Mechanics as a branch of natural philosophy... Sommerfeld's *Mechanics* is to be most warmly recommended." —*Science Progress*

Volume 2, 396 pp.

Mechanics of Deformable Bodies

Review : "... bound to widen the reader's horizon and increase his understanding of the physical significance of important methods and results." —*Journal of Applied Mechanics*

Volume 3, 371 pp.

Electrodynamics

Review : "... the material is beautifully balanced and makes the book... the best text available in this country for a graduate course in electrodynamics." —*Review of Scientific Instruments*

Volume 4, 383 pp.

Optics

Review : "This book bears the mark of the 'master theorist'... junior and senior physics majors... would acquire a better understanding... a more humble appreciation for physics from such a book." —*Journal of the Franklin Institute*

Volume 5, 401 pp.

Thermodynamics and Statistical Mechanics

Review : "... in a class by itself... It should be an excellent text for a graduate course in thermodynamics." —*Physics Today*

Volume 6, 335 pp.

Partial Differential Equations in Physics

Review : "... skillful handling of complex problems by the use of a minimum of mathematical formalism and a maximum of physical intuition." —*Science*

The Direct Observation of Dislocations

By **S. Amelinckx**

- presents the first complete review of all known methods for detecting individual dislocations in solids under study
- discusses crystal growth and evaporation, etching, decoration, decoration-etching, birefringence, x-ray diffraction, electron microscopy, and diffraction
- theoretical background is developed and its use is illustrated by specific, representative examples

Summer 1964, 487 pp., 121s. 6d.

The Many-Body Problem

Volume II

Edited by **E. R. Caianiello**

- contains the lectures delivered at the Fifth International Spring School of Physics at the University of Naples, 1963.
- provides an authoritative, up-to-date account of the developments of the last few years
- covers fundamental and applied aspects of the problem

Fall 1964, about 300 pp., 87s.

Star Evolution

Edited by **L. Gratton**

- gives an overall picture of the present state of the subject
- covers evolution, construction of stellar models, associations and very young clusters, stellar stability, the problem of Eta Carinae, stars with helium-rich cores, stellar hydromagnetics, the evolution of close binary systems, theoretical models for the pulsations of Cepheids, nuclear astrophysics, notes on cosmic radiation, etc.

1964, 488 pp., 132s. 6d.

Advanced Plasma Theory

Edited by **M. N. Rosenbluth**

- presents the elements of the theory of high-temperature plasmas
- includes kinetic, general stability, gas discharge, and nonlinear theories; boundary layer problems in plasma physics, topics in microinstabilities, instabilities due to finite resistivity or finite current-carrier mass, adiabatic invariant of the harmonic oscillator, and the gyration of a charged particle

September 1964, 270 pp., 78s.

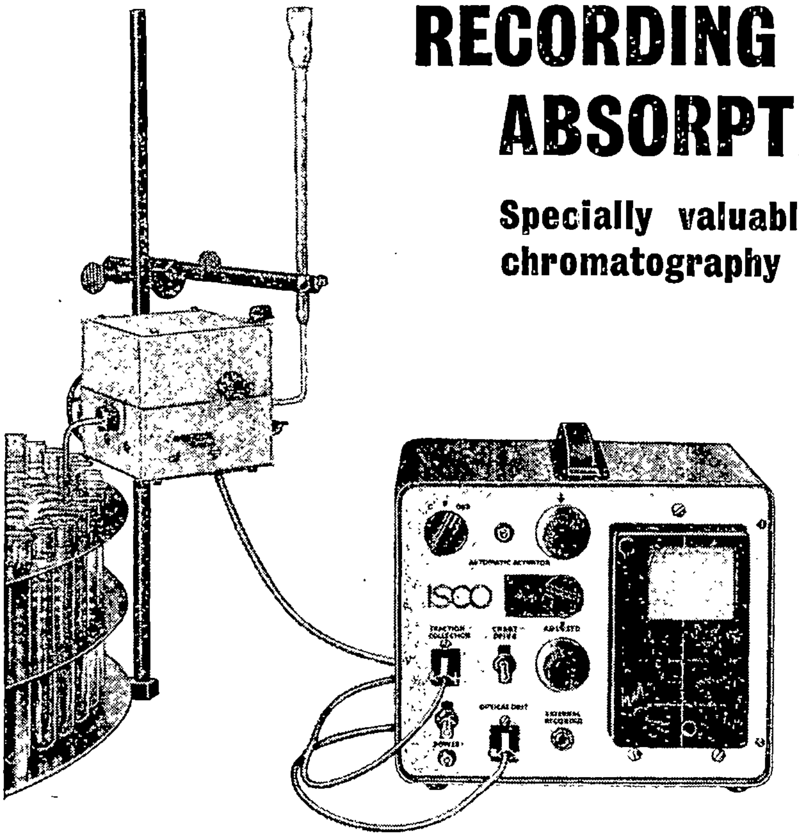
RECORDING ULTRA-VIOLET ABSORPTION ANALYSER

Specially valuable for preparative column chromatography



The ISCO Model UA Recording Ultra-violet Analyser automatically actuates the fraction collector, to deposit each UV-absorbing fraction into a separate tube, and simultaneously records the peak. Volumetric or timed control are additionally incorporated.

Peaks from under a minute to over an hour's duration are resolved equally well, thus preventing cross-contamination or dilution of the smaller fractions.

The UV flow analyser records in two ranges of absorbance (optical density or minus log transmittence) and operates on one wave-length of very narrow bandwidth (254 mμ).

The illustration shows the Ultra-violet Analyser and Strip Chart Absorbance Recorder connected to an ISCO Model A Fraction Collector.

Write or phone today for our leaflet on ISCO apparatus for column chromatography.

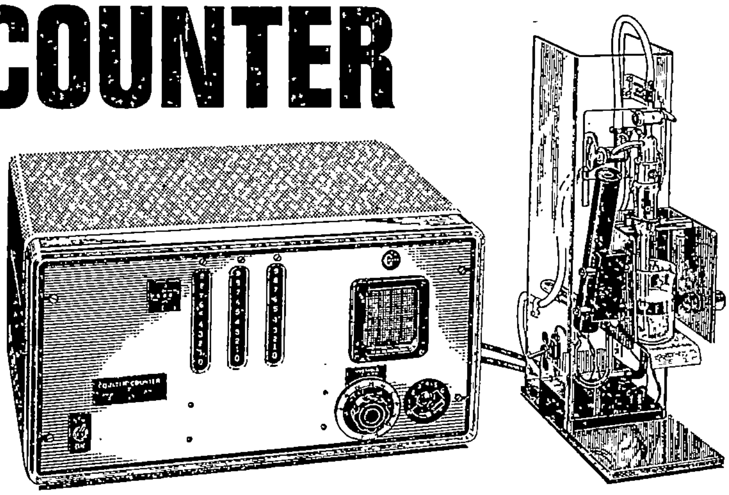
PARTICLES SIZED AND COUNTED BY

THE COULTER COUNTER

Party games may require twenty questions and a panel of experts, but the question of particle size analysis can be answered rapidly, simply and accurately by one person with a Coulter Counter. Whatever your field of activity, the clue to your particle problem (from 0.3 microns upward) can be solved automatically at 5,000 particles a second. Our technical staff are always ready to advise you on your counting and sizing problems.



Write or phone for further details.

Patents issued and/or pending throughout the world.

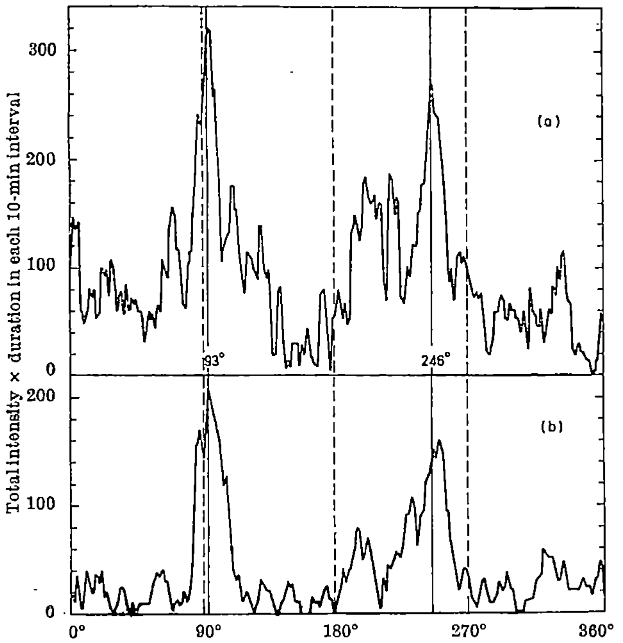

Fig. 3. The dependence of Jupiter's emission on the position of *Io* when (*a*) the Earth was ⩾9° to the east of the Sun as seen from Jupiter and (*b*) the Earth was ⩾9° to the west of the Sun as seen from Jupiter

define *Io*'s position, the peaks of Fig. 2 could be shifted by as much as ± 11°.

To test this, all cases when the Earth was more than 9° to the east of the Sun (Fig. 3*a*) were compared with all cases when the Earth was more than 9° to the west of the Sun (Fig. 3*b*). Clearly, the two highest peaks do not change their positions appreciably. Hence, the effect as detected on Earth depends on the position of *Io* relative to the Earth–Jupiter line.

Table 1
Co-ordinates of:

Io	Jupiter	Relative intensity
85°	115°	940
85°	145°	860
235°	225°	860
235°	335°	660

The apparent control of the emission by *Io* is far more complete if only events showing emission at frequencies ⩾ 30 Mc/s are considered. This is illustrated by Fig. 4, which is a re-analysis of the data in Fig. 2, selecting only events at the higher frequencies.

The relation of this analysis to earlier work on Jupiter's rotation is obviously important. A grid was constructed in which the vertical lines represented Jupiter's System III longitudes and the horizontal lines represented *Io*'s angular departure from superior geocentric conjunction. (*Io*'s orbit is circular and its velocity uniform except for small perturbations, so that times and angles are interchangeable.)

Each disturbance was plotted as a line on this grid and the total line-length in each 10° × 10° square calculated. Intensity '2' lines were counted twice, and intensity '3' lines three times. The results are shown in Fig. 5, the main features being confined to two quite limited portions of the map. The co-ordinates of the squares having highest intensities and their relative intensities are given in Table 1.

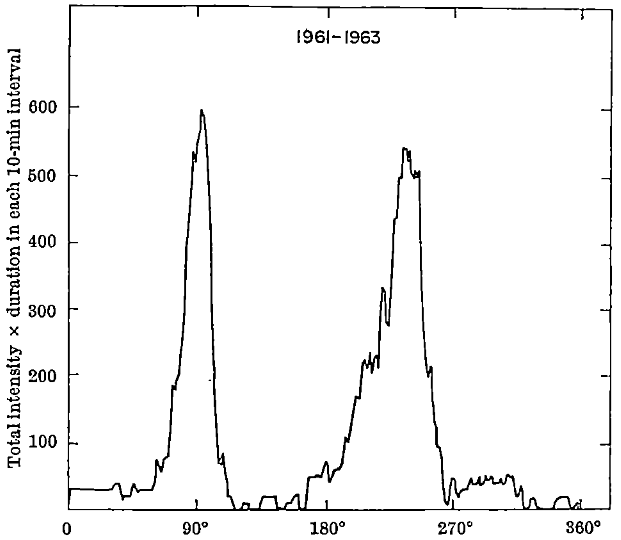

Fig. 4. Dependence of Jupiter's emission on the position of *Io* when only cases having top frequencies ⩾30 Mc/s are considered

Fig. 1 shows that, for the 600 cycles of *Io* represented, the highest peaks shift in position by less than 20°. The 2,548·5-min period chosen is therefore accurate to better than one part in 10,000, making it unlikely that the result is fortuitous. It cannot be the result of a direct coincidence with Jupiter's period of rotation, the ratio being 4·28 : 1. Warwick, in private discussions, has suggested that, because observation periods are spaced by about 24 h, the third harmonic of 24 h may beat with Jupiter's rotation period to give the observed effects. This would require a mean spacing of observation periods of 24 h 7·5 m, about 1 per cent longer than the mean spacing of 23 h 56 m. While this and other possible beats require close examination, it will obviously be difficult to match the sharply defined peaks which are observed.

There is a possibility that Satellites II, III, IV (Europa, Ganymede and Callistro) contribute to this effect; but in view of the approximate 1 : 2 : 4 : 8 ratio of the periods of the four satellites, it would require a more sophisticated treatment than that given here to reveal the extent to which they are involved. It is at least certain that *Io*'s

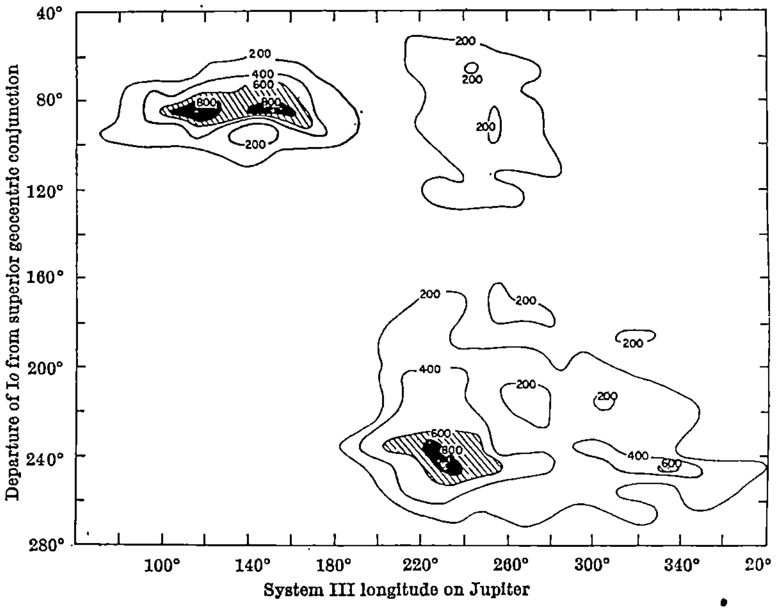

Fig. 5. The relationship between the position of *Io* and the orientation of Jupiter for the reception of decametric emission at the Earth

period has much the strongest influence. The very small Satellite V, which is the closest satellite to Jupiter's surface, has a period within 0·1 per cent of half the mean period between observations and consequently all parts of its cycle are not equally represented in one year. Since the observations are not equally distributed throughout each year, or between years, it is impossible to deduce whether Satellite V has a real effect or not. Once again, however, it is safe to conclude it is not responsible for the influences attributed to Io.

It is perhaps premature to consider why Io should influence Jupiter's radiation until other causes of a 2,548·5-min periodicity are eliminated. However, assuming that Io is responsible, then it seems possible that only one main 'source region' on Jupiter exists, and that the orientation of the line joining source and satellite determines whether the radiation will reach the Earth. This concept requires a considerable revision of ideas on the origin of the radiation, and probably of the orientation, of Jupiter's magnetic field.

I thank Dr. James W. Warwick, the High Altitude Observatory and Colorado University for permission to use their Jupiter results; Dr. Walter Orr Roberts for inviting me to the National Center for Atmospheric Research, Boulder, Colorado, where this work was carried out; and Dr. E. G. Bowen for his advice.

SCIENCE AND MANKIND*

By S. P. CHAMBERS, C.B., C.I.E.
Chairman, Imperial Chemical Industries, Ltd.

IF you look up the *Oxford English Dictionary* or the *Shorter Oxford English Dictionary*, you can get quite lost looking for any definition of science; almost everything seems to be covered, including any craft, trade or occupation or any branch of learning or skill. The best we can do is take from the *Oxford Dictionary* a definition of science in a more restricted sense which reads as follows: "A branch of study which is concerned either with a connected body of demonstrated truths or with observed facts systematically classified and more or less colligated by being brought under general laws, and which includes trustworthy methods for the discovery of new truths within its own domain". Even that is very general and seems to bear little relationship to all those branches of science, for example, mathematics, physics, chemistry, which we think of when we talk about science. Nevertheless it is important to recognize that when we are considering the impact of scientific thought and scientific discovery on mankind we must avoid putting the various branches of science into water-tight compartments. The body of scientific knowledge to-day is so vast that individuals must specialize in one sector or another; but the impact of discovery in one field on another can be seen in almost every walk of life.

It is for this reason that, while concentration on one aspect of science in a narrow field can be rewarding in that it may lead to fresh discoveries in that field, nevertheless it is the relationship of discoveries in some fields to the whole body of scientific knowledge which really matters.

Those of you who have been interested in the history of science must have been struck by the unevenness of the progress made in different fields over the centuries. In mathematics great progress was made centuries ago, and the same is true of discovery in the fields of astronomy and elementary mechanics. But in other fields, of the most vital importance to humanity, centuries passed before anything of great value was discovered.

In general, the need for protection against enemies, particularly human enemies, seems to have been the incentive for the application of science to the development of both offensive and defensive weapons; specially tempered metals for armour, gunpowder, cannons and cannon balls are obvious examples. The modern equivalent is the application of science to warfare on a world-wide scale at enormous cost, including the cost of developing nuclear weapons.

In the eighteenth and nineteenth centuries, with the Industrial Revolution, there was a great acceleration in the rate of progress in the application of science to more peaceful pursuits and a recognition of the immense benefits to be gained by applying scientific methods to almost every activity which could put up standards of living. By the use of mechanical power, the productivity of many industrial operations was raised sharply. The power was, for the most part, derived from coal, the energy of which was harnessed mostly by the use of steam engines. Standards of living throughout the World have indeed been improved tremendously by the application of science to industrial production, using the word 'production' in its widest sense to include transport and distribution.

One of the great problems, and it is still with us in one form or another, is that the advantages of more scientific production are not evenly spread throughout the population, and some sections may at first suffer through the consequential unemployment of those whose jobs have disappeared because of mechanization. The famous 'Luddite' revolts in which new textile machinery was smashed afford an illustration of the hardships and bitterness which industrial progress can cause. In the long run, anything which increases man's output of the things which man wants must put up the standards of living; but for those who are adversely affected it is the short run that counts. As Lord Keynes, the economist, once said: "in the long run we are all dead". The solution of this problem lies in the humane treatment of those who suffer from changes of this kind, and assistance which enables them to fit themselves with new skills and new jobs for which there is a demand in the new conditions. The solution can never be the holding back of economic progress based on scientific discovery. If we jump now straight from the remarkable surge forward in the eighteenth and nineteenth centuries to conditions as we see them to-day, it is clear that, so far from the Industrial Revolution having come to an end, it is continuing and, if anything, at an accelerated pace.

Perhaps the simplest illustrations are in the field of transport, whether on land or in the air. The steam engine has given way to the Diesel engine and the fast electric train; in the air we have seen successively the progress from the simple, slow bi-planes of fifty years ago to heavier, faster, multi-engine pistoned planes, to turbo-jets and pure jets. Returning from Australia two weeks ago the captain of the aircraft in which I was travelling announced as we left Rome that owing to a strike of air control officials in Paris we would have to make a detour of an extra 100 miles over Germany; that, he said, will take us another ten minutes. Now there is the prospect of further change from sub-sonic to super-sonic air travel.

In the manufacturing industry there is similar progress, particularly in those sections of industrial production which lend themselves to large-scale operation.

---

* Substance of an address to the fifth Annual Conference for Sixth Forms, Eltham Green School, on July 14.

Here again, there has been a steady transition from manual operation to mechanical operation and from the simple power-driven machinery of the nineteenth century to far more complicated and more efficient machinery, driven by electric power, whether generated from coal, oil or atomic energy. To-day we are now seeing the introduction of computers into almost every aspect of industrial operations, including research, production, distribution and the control of marketing operations. Some industrial plants to-day are being controlled by computers which not only determine which are the best operating conditions but set the various plant controls so that these conditions are achieved.

Perhaps I can give here an illustration of the inter-relation of different scientific techniques in practical applications in modern industry. Most of the simple starting materials for the synthesis of organic chemicals are now obtained by pyrolysis (or cracking) of low-boiling petroleum fractions usually referred to as naphthas. These various components have to be separated and purified to make them suitable for further chemical operations, and this is done mainly by fractional distillation at very low temperature and high pressure, an operation which would not have been possible without the tremendous progress which has been made in fields of refrigeration and the physics of mass transfer.

At present the main product from the Imperial Chemical Industries crackers is ethylene, the raw material for polythene; but other gases, including methane, propylene, butylene and so on, are produced—about ten in all—together with petrol and some heavy material. Some of the gases produced are more valuable than others, and it is frequently necessary to vary the proportions of the components in the primary cracker gas: this can be done by modifying the reaction conditions. To do this effectively, however, rapid analysis of the primary gas is essential, and it is only relatively recently that this has been made possible by the use of the techniques of infra-red, ultra-violet and mass spectroscopy which can give an answer in minutes whereas older chemical methods required hours. Thus we have here a case in which important advances in the chemistry of naphtha cracking could not have been put to full industrial use without advantage being taken of equally important discoveries in the fields of physics and physical chemistry.

Another example is nylon, which was originally discovered by Carothers in the United States, who was engaged in highly fundamental research on what are called 'long-chain polymers'. This was a most important discovery, but by itself it could never have led to the universal use of nylon which we see to-day. A whole series of new chemical processes had to be uncovered in order to be able to produce nylon cheaply enough from readily available raw materials. New dyes had to be found which would provide the requisite range of colours for this new fibre. Entirely novel machinery had to be developed for spinning the fibre and many basic investigations in the field of physics had to be made to elucidate the relationship between molecular alignment and mechanical strength, the effect of cross-sectional geometry on the handle of the final fabric and so on. Control of the spinning, drawing and twisting of fibre processes would have been impossible on a large scale but for the development of many new physical techniques.

The work of original discovery is one step only; the scientific work of developing a product for full-scale production goes on for years rather than months.

All this work in industry requires a very high level of scientific knowledge and inventiveness. For able men the work is exciting and rewarding.

It is natural that I should be thinking more of industrial production than of other aspects of man's activities; but there has, of course, been great progress in many other fields. Medical science, for example, is to-day moving forward rapidly and, with a far better understanding of all the factors that determine health in both man and other animals, some of the worst diseases which plagued the world for centuries have little more than historical interest to-day. Others, such as malaria, are beginning to disappear even from those countries, such as, for example, India, where they have probably been the greatest source of human misery. Much remains to be done; there are still diseases prevalent in temperate or tropical climates for which there are no adequate remedies.

Agriculture is also becoming far more scientific than it was, and the changes from hand-work to mechanical work have their counterparts in a growing understanding of botanical conditions and of the means of getting rid of plant diseases and putting up productivity in terms of food crops. But the haphazard use of chemicals for the destruction of weeds or insect pests can do as much harm as good. Here again, the right attitude is not to condemn all herbicides and pesticides but to produce and use these substances in a scientific way. Only after patient scientific analysis, experiment and trials can we be sure of their long-term effects. Properly used, the resulting benefit can be dramatic. For example, a few years ago Ghana was faced with a cocoa blight which threatened almost her whole crop. That crop represented half of Ghana's export trade and was therefore vital to her economy. The timely erection of a small insecticide plant and the application of this insecticide at the right time saved the whole crop. Some of the greatest crop disasters in history which involved starvation on a large scale would have been avoided if our present knowledge of plant diseases and their remedies had been available then.

The problems of water erosion and of wind erosion to the soils of vast areas in the Americas, Asia, Africa and, perhaps to a lesser extent, Europe are also other cases in point. To-day new methods are being devised whereby weeds and the remains of a previous year's crops can be destroyed by chemicals which leave no harmful residues in the soil. Following this destruction of the existing vegetation, it has now been found possible to sow fresh seed directly into the ground without ploughing, and this means that the fibrous materials and roots from the older plants remain in the ground and act both as food for the new plants and as a protection against erosion, whether by wind or water. The possibility of increasing food production substantially on large areas of land which were, and are still becoming, steadily impoverished by erosion is of the greatest importance. By the adoption of more scientific practices in agriculture, including the application of appropriate fertilizers, the fears expressed by Malthus and others that food production would be unable to sustain the growing population of the world can, I believe, be dispelled.

There is, of course, the other side of this particular problem, namely, the growth in population which some pessimists still think will outstrip any possible food production. Here again, I think the pessimists will be proved to be wrong. It has already been demonstrated that as the standards of living of people in a particular area rise above a certain level, there is a tendency for the rate of growth of population to fall, and I am sure that other methods will be found to keep the population of the World within reasonable limits.

I have ranged over many activities in a very sketchy manner to indicate that there are openings and opportunities for scientists in many walks of life. When, however, a boy or girl entering a university to read for a science degree is thinking about his or her career after graduating, other questions are bound to arise.

Sometimes fairly sharp distinctions are drawn between pure science and applied science. There are, of course, certain aspects of scientific work which can be regarded as pure in the sense that they are of general or, indeed, universal application. This is certainly true of some scientific work in the field of, say, mathematics, physics or astronomy; but the borders between the pure and the applied are not clearly defined, nor should they be.

Moreover, I think it is desirable to dispel any idea that the 'purer' side of science is in some way superior or requires a higher intellectual ability than the more applied side. There may be in some minds a vague idea that the pursuit of scientific research solely for the sake of adding to the sum of human knowledge is more intellectually satisfying than a career which is concerned with scientific research leading more directly towards something of material value in our daily life. Personally, I would regard such a notion as false.

In many countries the importance of scientific work in the great task of raising living standards is clearly recognized, and there is, among scientific workers engaged on work which may lead to the reduction of disease and the improvement of nutrition, a sense of purpose which is at least equal to that of the pure scientist seeking knowledge for its own sake. This is particularly true of such scientific workers in poorer countries such as India or Pakistan.

It does sometimes happen that a scientist engaged in purely academic work discovers something which is of outstanding practical importance. On the other hand, the need to solve some practical problem, whether in the sphere of industrial production, transport, agriculture, medicine, or in some other aspect of our daily life, will often be the spur to work of a more fundamental character. Indeed, so often it is the practical problem which leads us to realize that our basic knowledge is imperfect and which can give a sense of purpose and direction to this kind of research.

In the chemical industry the competition between one large chemical company and another which reveals either relative weaknesses in existing products or the possibility of new products very often throws up work to be done in our laboratories which is of a highly scientific character, the results of which can sometimes have an application far beyond the solution of the original problems. The same happens in the drive to improve the processes for the manufacture of existing products. Once embarked on a revolutionary method of producing something which has been made by traditional methods for years, we find the problems to be solved can lead back to basic questions related to the structure of molecules or to the mechanism of reactions which occur often under abnormal conditions of temperature or pressure.

I mention this because I think it is most desirable to get away from any idea that the most brilliant scientists should remain in research establishments in universities and should not go into industry. There is need for such scientists both in the universities and in industry. From the over-simplified statements sometimes made, one might imagine that discoveries of new products are made only or mainly in universities, leaving industry to take the new product, to develop it and then to produce it on full-scale plants. In practice, most discoveries of new products are made in the laboratories of industrial firms where the scientists are struggling to solve particular problems arising from the production and sale of their existing products. This is true, for example, of polythene, nylon, 'Terylene', 'Paludrine' (a drug which is of outstanding importance in combating malaria), and of a whole range of chemical products. In the Imperial Chemical Industries alone we are spending £18 million a year on scientific research and development work. There is room, therefore, in industry for growing numbers of scientists, and the better the scientists the better it is for industry.

Science in one form or another permeates the whole of industry and transport and has indeed entered the sphere of office work. We have in the Imperial Chemical Industries more than half a million stockholders, and there are thousands of transfers of stock every year which have to be recorded in the Company's stock registers. Twice a year dividends have to be paid to the stockholders on the registers. This used to require a large amount of clerical work in preparing twice a year the cheques, or 'dividend warrants' as they are called, and many people were employed on this rather laborious work. To-day the whole of the stock register has been put on an electronic computer which itself produces the dividend warrants complete with the names and addresses of the stockholders. The number of people needed is much smaller; but there is a growing need for electricians who can build and maintain such computers, and for operators who can devise what are known as the programmes for the computers. In other words, the trend is for a reduction in routine work and an increase in work which requires higher educational standards, and particularly higher standards on the scientific side.

This transformation from hand-work to mechanical work and computer-controlled work is going on steadily throughout large-scale industry. There will, of course, always be smaller businesses where it is more economical to use less highly developed and complicated processes; but in many sections of industry and commerce the movement towards scientific methods of control and accounting is accelerating rapidly. This movement extends to banking and insurance, where much of the routine work is being taken over by machines and electronic computers.

In the manufacturing industry, scientific progress invariably means that fewer operatives are needed for the same or a larger output of products. Sometimes large plants are involved, but not always. In one case in Imperial Chemical Industries a revolutionary method of producing the gases from which ammonia is made has meant a great reduction in the amount of plant needed as well as a reduction in the number of process workers. This ammonia is needed for agricultural fertilizers and has many other uses. Until a few years ago, a plant of 20,000 tons would have been regarded as large and would have required a whole battery of coke ovens as a first step towards producing these gases. To-day we are scrapping plants put up only a few years ago and putting in two, each of 300,000 tons a year, and plants with this tremendous capacity look small by comparison with those which a few years ago produced a mere fraction of that quantity. Externally a modern plant of this kind appears to consist of a lot of pipe-work carrying gases, some large cylindrical reactors, and other plant which is completely enclosed, and therefore appears to contain no machinery in the accepted sense or anything other than gases and a catalyst to assist the reaction. The whole plant is controlled from a control room with a large number of dials showing flow rates, temperatures and pressures at different stages in the process. There are no manual workers in the ordinary sense, just one or two people in the control room watching the dials, and the men required for the maintenance of the plant. This is becoming a common pattern in sections of the chemical industry, and indeed a similar pattern is emerging in other industries. Routine work of a repetitive character and laborious manual labour are both on the decline; but the need for intelligent men who can understand and control highly automated operations is growing.

Other questions arise in this connexion which one may feel are not of a scientific character; but they are, in fact, of importance in considering the place of scientists in industry. With the growth of the size of industrial organizations to cope with the growing scale of production, the scientist may find himself one of a number of employees in a large concern such as Imperial Chemical Industries. One may wonder whether life in such a concern is likely to be less interesting than in a smaller organization, and perhaps feel that scientists may get lost in a vast bureaucratic machine. This, in fact, is not true. It is now recognized that there is a growing need to apply scientific methods to the organizational problems of a large business. The object is to give every man full scope to do his work to the best of his ability and with the minimum of detailed instructions. An intelligent man works better if he is given personal responsibility for his section of the work. Some instructions, some control and a good deal of co-ordination there must be, but this need not be inconsistent with the freedom of the individual to get on with his own job largely on his own responsibility. Personal relationships between different people in a large organization are of outstanding importance, and the object is not only to get the highest productivity in the direct or physical sense but also to get workers of all kinds, and particularly the higher grade workers, including scientists, to do their work with a sense of purpose and enthusiasm. No organization is in this respect perfect, and the task of getting many people to work happily and harmoniously is never finished. Indeed, this task of organizing and co-ordinating the work in the many sections of a large organization requires men of the highest intelligence and character.

So much of the work has a scientific foundation that it is desirable that many of the higher posts, probably the majority, should be filled by men with a scientific background. It is quite wrong to assume that the place of the scientist in industry is only in the laboratory, or that the scientist need not bother much about matters outside his particular scientific field. All the operations of a company which is making products of importance to world trade have to be closely co-ordinated, and there is need for an understanding of the relationships between the marketing of products, their manufacture and the research and development work that goes on all the time to improve the products, to reduce their cost and to find new products. In Imperial Chemical Industries we employ some thousands of men and women with scientific degrees. A proportion of these work in the laboratories; but many of them are engaged on other operations, controlling large sections of work which may be on the production side or on the marketing side, or their tasks may straddle all the operations, from manufacture to sale, of a group of products.

A good scientist who can comprehend not only the problems in a laboratory but also the problems involved in determining the scale of production, the erection of a new plant which may cost millions of pounds, or in the control of men either at home or overseas, is the kind of man or woman which is needed in the higher posts in industry. The careers open to scientists are varied and interesting, particularly for those who reach a high academic standard in their particular field of science and also have the capacity to understand the relationship of this work to all the other work in a large industrial organization. The chemical industry has been uppermost in my mind, but much of what I have been saying is equally relevant to other industries, such as aircraft manufacture, the metal industries, radio, television, transport, and so on: the requirements of high academic standards plus the right character are similar throughout modern industry.

I have said that the specialist scientist is a better man if he has also a good understanding of the relationship of his work to the world of science as a whole, but even this is not enough. An understanding of the way in which the country's economy works and, if exports are involved, of social and economic conditions throughout the World is invaluable. I am not suggesting that every chemist, physicist or engineer must also be an economist; but I do know that those chemists, physicists or engineers who have a broad background knowledge of economic principles can do their work with a better understanding of its significance and are likely to be better candidates for higher executive posts where they have to control and co-ordinate work over a wide field than the specialists who lack any such background. The future for scientists in industry is bright; the best prospects are for those good scientists who have just something more than their scientific qualifications.

There is another general point which is inescapable. With the growing productivity of human effort as scientific methods are applied throughout industry and commerce, we shall be able to produce the material things of life with ever-shortening working hours, even if this shortening is a gradual process, extending over many years. The shortening of hours, whether we are considering either the shortening of the number of hours worked per day, or the number of days worked per week, or the number of weeks worked per year, will mean, I believe, an increase in leisure time, and with rising standards of living an increase in the money that can be spent in leisure time. This itself will raise certain problems. In particular, how will these leisure hours be utilized? This is a matter which has to be answered by each individual for himself; but I am convinced that higher educational standards can make for a greater enjoyment of life as a whole and not only that part of life which is concerned with work. In cultural matters, in the appreciation of art, music, literature, the better and broader the education, the greater is the capacity for appreciation and enjoyment of all the things that can be done in leisure hours. As our material standards of living rise, the need to preserve a balance in education between science and the humanities and arts becomes more apparent.

OBITUARY

Dr. M. J. Cross

MICHAEL CROSS died in an air crash in Tennessee on July 9 on his way to a scientific meeting.

Cross possessed a rare combination of fine qualities of character and intellect, and his death at the age of thirty-seven is a serious loss for medical research. He received his early education at Cranley School, where he won an open exhibition and the St. Nicholas Scholarship. During 1944–47 he was in the Royal Naval Volunteer Reserve which he left as sub-lieutenant. In 1947 he went up to New College, Oxford, with an open exhibition and read for an honours degree in chemistry. After graduating in 1951, Cross took up research in Oxford as Guinness Research Fellow in microbiology, working under Prof. D. D. Woods, and in 1954 he obtained the D.Phil. degree for a thesis on the metabolism of serine by micro-organisms. At first his work was concerned with the interrelationship of carbon dioxide and citrovorum factor in the requirement for serine by *Leuconostoc*; he showed that carbon dioxide prevented the breakdown of citrovorum factor. Later he worked on the synthesis of methionine by *Escherichia coli*, and he was largely responsible for the development of a cell-free system which has been the basis for many subsequent advances. The results of this work were published between 1951 and 1960 in a series of papers in the *Journal of General Microbiology* and in the *Biochemical Journal*.

Although Cross was then well on the way towards a fine career in biochemistry he took the unusual step of becoming a student again to study medicine in the Oxford Medical School. During that time he kept himself up to date in his earlier subject by tutoring his fellow medical students at New College in organic chemistry. After graduating in December 1959 Cross was successively house physician to Prof. L. J. Witts at the Radcliffe

Infirmary and house surgeon to Mr. Frank Ellis at the Churchill Hospital. Cross's work in clinical medicine was highly thought of and he was happy doing it. However, it became clear to him that his deepest interests lay, after all, in research. His successive training in chemistry and medicine was ideal for starting him in medical research with every hope that he would be able to make important and useful contributions to knowledge. From what he had already achieved when he died, this hope was fully justified.

Cross often said that he would like any research on which he was engaged to have a good chance of being clinically useful. He was therefore happy when he was asked to join an investigation into biochemical aspects of blood coagulation and thrombosis. For this he came to the Department of Pharmacology at the Royal College of Surgeons of England in London. The College made him Research Fellow, and he was supported by the Medical Research Council. Soon he had his first success by discovering a way of stabilizing thromboplastic activity in plasma and of separating the activity by high-speed centrifugation. The active material appeared to react directly with prothrombin, and Cross showed that the kinetics of the reaction were as might be expected if 'plasma thromboplastin' were an enzyme. For the first time, therefore, it became proper to describe 'plasma thromboplastin' as a substance with the properties of an enzyme and, hence, as plasma prothrombinase. Cross showed further that when centrifuged in the absence of calcium plasma prothrombinase splits into two fractions. One fraction is heat-labile and contains protein: the other resists heating and contains phospholipid. In this way Cross confirmed experimentally the well-known suggestion made by Macfarlane many years ago that 'plasma thromboplastin' consists of two components, one a protein and the other a lipid; and Cross showed that the components are bound together by calcium.

Cross then became involved in a study of the factors that control the adhesiveness of blood platelets. Interest in this had just been stimulated by the discoveries that platelet adhesiveness is greatly and specifically increased by adenosine diphosphate and that this increase is prevented by other, closely related, substances. Cross made important contributions to the clarification of these effects, including the demonstration that they require a plasma protein which is present in the fibrinogen fraction. It now seems that deficiency in this protein causes von Willebrand's disease. Most of Cross's work in this field has been published in *Nature*, in *Thrombosis et Diathesis Haemorrhagica*, and in the *Journal of Physiology*.

From September 1963 until his death Cross and his family had been living in the United States. He went there with a Fullbright Travel Scholarship as Buswell Research Fellow in Biochemistry of New York State University. With Dr. Douglas Surgenor, first in Buffalo and then in Woods Hole, he continued working on the identification of the plasma protein already referred to and on other important subjects. He was invited to contribute to several conferences, including the annual symposium on "Blood" at the Mayo Clinic. Britain could have had no finer representative in the United States than Michael Cross. Although, like other scientists, he must have had tempting offers to stay, there was never any doubt that he wanted to come home. In September he was to have returned to the Royal College of Surgeons to join the new Thrombosis Research Group of the Medical Research Council.

In his work Cross combined enthusiasm with cautiousness in establishing and interpreting his experimental results. He was full of ideas, but his careful chemical training never allowed them to run away with him. He was independent, but very co-operative.

Cross made friends with all who knew him. He was the essence of kindness and helpfulness. He had the ability to get on well with people whose opinions were very different from his; this was important, because he had strong views on social affairs. Almost always he was cheerful, exuberant really; when something went wrong and he became temporarily less than completely happy—one never saw him gloomy—it was still good to be with him because his emotions were so honest, spontaneous, and open.

Cross had a happy and settled family life in a village where he was very much part of the landscape. He played cricket and shove-ha'penny; and quietly he visited the lonely old people to cheer them up. His family, friends and country suffer grievously by his death. Indeed it is almost impossible to believe that this exceptionally lively, happy, very-present figure will not be returning to us. G. V. R. BORN

NEWS and VIEWS

Sprengel's Pump

IT is now almost 100 years since Herman Sprengel developed his mercury air-pump—an invention which he described to the Chemical Society in 1865, and one which proved to have an important influence on the development of both science and industry in the latter part of the nineteenth century, especially in the development of the electric lamp, discharge tubes, the discovery of the so-called 'inert' gases, etc. Sprengel, the man, has gained little notice from biographers, but his mercury pump has been the focus of much attention. Born in Schillerslage, Hanover, on August 29, 1834, Sprengel was educated first at Göttingen and then Heidelberg Universities. Coming to Britain, he worked for three years as an assistant in the chemical laboratory of the University of Oxford, and then as assistant in the laboratories of Guy's and St. Bartholomew's Hospitals. During 1865–70 he was employed in the Farmer's Chemical works and became a naturalized Briton. He devoted much time to detonation and explosives, and was the first to direct attention to the value of picric acid as an explosive when fired by a detonator. For the rest of his life he was engaged on his own inventions and patents, but his *chef-d'œuvre* was his pump, especially once he became one of the eminent men fascinated by the power of the vacuum. Toricelli, Von Guericke with his famous Magdeburg hemispheres, Boyle, Papin, Geissler and Töpler all joined this 'cult of the vacuum', while Röntgen, Crookes, Dewar, Langmuir and Fleming continued the theme with the aid of Sprengel's pump. Sprengel was elected a Fellow of the Royal Society of London in 1878. Mercury with its stable nature, its inertness towards gases and vapours, certainly proved a boon before the advent of high-vacuum pumps, and made it possible for Sprengel and his followers to show up the short-sightedness of Lear's reply, "Why, no, boy; nothing can be made out of nothing" when the Fool questions, "Can you make no use of nothing, nuncle?".

Social Psychology in the University of Sussex: Prof. Marie Jahoda

MARIE JAHODA, who is at present Head of the Department of Psychology and Social Science at Brunel College, studied psychology at the University of Vienna, where she received her Ph.D. in 1932. In Vienna she was assistant director and then director of a research institute. In 1937 she came to England and soon afterwards was awarded the Pinsent-Darwin fellowship at the

University of Cambridge. After studying a subsistence production scheme for unemployed miners in South Wales, and the impact of factory life on the personality of school-leavers, she joined the first team of the War-time Social Survey as assistant editor. In 1945 she went to the United States, where she was first associated with the Research Department of the American Jewish Committee. After spending a year at the Bureau of Applied Social Research at Columbia University she took an appointment at New York University, and she was professor of psychology and director of the Research Center for Human Relations when she left New York in 1958 to return to Great Britain. Joining Brunel College as Nuffield Research Fellow, she played a major part in founding the first Psychology Department in a College of Advanced Technology, and instituted a sandwich course for the education of professional psychologists. Dr. Jahoda is a member of the Council of the British Psychological Society. She takes an active interest in the systematic approach to social issues and is a member of the Home Office Research Advisory Committee, the Television Research Committee and the Scientific Advisory Committee of the National Institute of Industrial Psychology. Dr. Jahoda has written numerous articles, and is co-author of *Die Arbeitslosen von Marienthal*, *Anti-semitism and Emotional Disorder*, and *Research Methods in Social Relations*. Her book *Current Concepts of Mental Health* appeared in 1958; *Race Relations and Mental Health* was brought out by Unesco in 1960; and *The Education of Technologists* was published in the spring of 1963.

Physical Geography in the University of Sheffield: Prof. R. S. Waters

PROF. R. S. WATERS, professor of geography in the University of Canterbury, Christchurch, New Zealand, has been appointed to the chair of physical geography in the University of Sheffield. Prof. Waters is forty-two. He entered the University of Reading in 1940, but his studies were interrupted by war service in the Royal Air Force. After training as a pilot in Canada he was engaged in meteorological flights from Iceland over the North Atlantic. Re-entering the honours school at Reading, Prof. Waters gained a B.A. degree with first-class honours in geography in 1948 and his M.A. in 1951. From 1950 until 1953 he was assistant lecturer in the University of Sheffield and in 1954 went to the University College of the South-West of England (now the University of Exeter) as lecturer. He took up his present chair at Canterbury in August 1962. Prof. Waters was senior geomorphologist in the Spitzbergen Expedition of the Universities of Birmingham and Exeter in 1958, and United Kingdom representative at the International Colloquium on Periglacial Geomorphology at Liège in 1959. He was a member of the New Zealand delegation to the recent International Geographical Congress in London and was organizer of a field symposium held during this Congress on the Pleistocene geomorphology of south-west England. Prof. Waters is secretary of the New Zealand Geographical Society and a member of a technical sub-committee of the New Zealand Committee on the International Hydrological Decade. His publications include papers on geomorphological mapping, periglacial geomorphology and on the geomorphology of south-west England. It is anticipated that Prof. Waters will take up his new appointment in the University of Sheffield early in 1966.

The National Research Development Corporation

IN a written answer in the House of Lords on July 28, the Minister of State, Board of Trade, Lord Drumalbyn, stated that the Government now proposed to seek powers to extend the scale and scope of the work of the National Research Development Corporation to enable it to contribute more effectively to industrial innovation and development, particularly development in which industry shared the risk. For this purpose legislation would be introduced in the next session to raise to £25 million in the first instance the Corporation's present limit of borrowing power from the Board of Trade. The legislation would also provide for a modification and extension of the financial and other conditions under which the Corporation operates so that, in partnership with industry, it would have greater freedom to promote the development and commercial application of new techniques. The Government had also investigated the opportunities presented by the techniques of automatic control of industrial processes and the problems which this might involve. As a result of a recent investigation by the Board of Trade, the Government was satisfied that there was need to co-ordinate, supplement and further stimulate existing activities. This would be the task of a small high-level steering group of officials which was being established under his direction. As a first task this group would urgently review the progress of automation in Britain and other countries and the probable future development of these techniques. In consultation with other interests concerned, it would also draw up a co-ordinated programme for promoting the activities of the various Government, professional, industrial and commercial bodies already at work in this field. With those measures simultaneously announced, arising out of the report of the Trend Committee (*Nature*, 203, 574; 1964). the Government believed that a substantial and practical contribution would be made towards solving the problem of how best to encourage and assist industry to apply commercially the results of research and technological advance.

Nuclear-powered Merchant Vessel

IN answer to a question in the House of Commons on July 30, the Minister of Transport, Mr. E. Marples, said that recently the Furness Shipbuilding Co., Ltd., and the Anglo Norness Shipping Co., Ltd., had approached him and the Secretary of State for Education and Science with the view of building and operating a large merchant vessel powered by a *Vulcain*-type reactor. Imperial Chemical Industries was considering the possibility of using the vessel if suitable terms could be negotiated. Discussions were in progress to see if agreement could be reached on arrangements for financing and organizing such a project. If satisfactory agreement was reached the ship would be built on the North-east Coast by the Furness Shipbuilding Co., and with a quick agreement the ship should be operational by 1968. Mr. Marples added that it was quite clear that the Government would have to play a considerable part in the project, and that the present stage would not have been reached without the research and development on which millions of pounds had already been spent. This information was also given to the House of Lords by the Parliamentary Secretary to the Ministry of Transport, Lord Chesham, on the same day.

Carriage of Dangerous Goods

IN reply to a question in the House of Lords on July 13, the Minister of State, Home Office, Lord Derwent, said that the United Kingdom was a signatory to the European Agreement on the International Carriage of Dangerous Goods, expected to come into operation within the next year. This comprised a detailed and comprehensive code, drawn up by an international group of experts, to ensure that international consignments of dangerous goods were packed and carried safely. Appropriate means for applying similar provisions to domestic traffic were being considered, but while any action should, to some extent, follow the lines of the international agreement, the latter did not bind internal traffic. He did not think that it would be appropriate to modify existing legislation, such as that covering the carriage of explosives, but that any legislation should be based on the international agreement when the final details were settled, probably within six months.

Research at the Home Office Police Research and Planning Branch

In a written answer in the House of Commons on July 24, the Secretary of State, Home Department, Mr. H. Brooke, stated that the principal subjects of research at present being undertaken by the Home Office Police Research and Planning Branch included: research into methods of dealing with serious and unsolved crimes, including an investigation into the possible extension throughout Britain of regional crime squads and criminal intelligence bureaux, and a study of criminal investigation techniques and improved scientific aids; an enquiry into the possible application of computers to fingerprints and other police records; an investigation of the policing of motorways and other through routes, including experiments with the use of a helicopter; investigation of the problem of devising a formula for accurately assessing police establishments.

Scientific and Technological Man-power in Britain

In reply to a question in the House of Lords on July 15, the Earl of Bessborough said that the output of qualified scientists had risen from 6,500 in 1959 to 9,600 in 1964, and that of engineers from 8,800 to 9,900 a year, giving a total of scientific and technological man-power nearly one-third higher than in 1959. This total of 19,500 compared with the 20,000 set as the target for 1970 by the Man-power Committee in its 1956 report.

Employment of Graduates

The report of the University of Glasgow Appointments Committee for the year ended December 31, 1963, records that while competition for appointments was more severe, generally this was met successfully (Pp. 26. Glasgow: The University, 1964). The demand for mathematicians, physicists and electronic engineers continued to be far in excess of supply, but chemists met a more difficult situation, and opportunities for geologists were hard to find outside South Africa. About 53 per cent of honours graduates in science took some form of postgraduate study; only 2 went overseas at that stage. Almost one-third of those with an ordinary degree in science entered the computer field. The number of men with honours degrees in arts or law entering industrial careers increased, but fewer with ordinary degrees did so. Only 39 honours graduates in arts and 50 men with ordinary degrees took up teaching, compared with 41 and 61, respectively, in 1962; for science the corresponding figures for 1963 are 28 and 36, and for 1962, 23 and 37. In November 1963 it was decided to separate the two functions of Appointments Secretary and Adviser of Studies in Science. For women students little change is noted in the general pattern of employment, although the number of openings in Scotland notified to science graduates rose from 34 to 59. Of the 307 graduating in arts, law, pure and applied science, 74 entered direct employment, 177 taking a teacher training course, an increase of 35, but there was a considerable drop in the proportion of honours graduates in science entering teaching, and none of those graduating with honours in mathematics (or mathematics and another subject) did so.

Regional Centres for Radiological Protection Services

The Ministry of Health and the Medical Research Council have jointly set up four Regional Centres of the Radiological Protection Service at Birmingham, Leeds, Manchester and Glasgow. These Centres can now be used in connexion with radiation surveys of radiological establishments and advisory services (including advice on plans of radiological establishments). It is envisaged that, later in the year, the Centres will provide other services, such as personnel film monitoring, calibration of radiation-protection meters and leakage tests of sealed radioactive sources. The Radiological Protection Service, Clifton Avenue, Belmont, Sutton, Surrey, will continue to provide services for establishments in south-east England. All establishments which at present make use of the film-monitoring and other services provided at Sutton will shortly be informed which Centres will provide future services for them.

World Health Organization Reports

The valuable information published from time to time in the Technical Report Series of the World Health Organization is so well known and widely appreciated that it is scarcely necessary to direct the attention of our readers to it. Expert committees of the Organization have recently issued seven Reports, all of which are of great interest. No. 271 (Pp. 18. 1 Sw. fr.; 1*s.* 9*d.*) deals with *Atmospheric Pollutants*. Report No. 272 (Pp. 52. 2 Sw. fr.; 3*s.* 6*d.*) is the tenth report of the Expert Committee on Malaria, and the continued success of the Organization's world-wide campaign against this disease is further discussed in detail in the *W.H.O. Chronicle* (18, No. 6; June 1964) under the title "Malaria Eradication in 1963", together with a map which shows at a glance the astonishing progress that has been made and the hopeful outlook for the future. In 1963 the seventh International Congress on Tropical Medicine and Malaria was held at Rio de Janeiro, and a note on this Congress appears in the *Boletin Chileno de Parasitologia* (19, No. 1; 1964). This Congress was attended by 1,236 experts from 65 countries. Technical Report No. 274 (Pp. 90. 3 Sw. fr.; 5*s.*) deals with *Biological Standardization*; No. 275 (Pp. 27. 1 Sw. fr.; 1*s.* 9*d.*) reports on *Psychosomatic Disorders*; No. 276 (Pp. 53. 1 Sw. fr.; 3*s.* 6*d.*) is on *The Prevention of Cancer*; No. 278 (Pp. 48. 2 Sw. fr.; 3*s.* 6*d.*) is entitled *Postgraduate Preparation of Health Workers for Health Education*. No. 277 (Pp. 69. 3 Sw. fr.; 5*s.*) is a valuable report by the Expert Committee on Helminthiases on *Soil-transmitted Helminths*, which are responsible for much illness, disability and economic loss among millions of human beings and domesticated animals. This Report discusses the extent and geographical distribution of these helminthic diseases, the factors which influence their transmission, their pathogenesis and clinical manifestations, the interrelations between the physiology and biochemistry of the parasites and their hosts, immunity to them, the techniques used to investigate them and methods of controlling them, together with recommendations for research. Copies of the Reports are available from the World Health Organization, Geneva, or H.M. Stationery Office, London.

The International Council of Scientific Unions

The May 1964 issue of the *ICSU Bulletin* includes a preliminary report of the tenth general assembly of the International Council of Scientific Unions, Vienna, November 22–29, 1963, with exerpts from the presidential address (No. 1. Pp. 64. Rome: International Council of Scientific Unions, 1964). There are also brief reports on meetings of the International Unions (Pure and Applied Physics, Geological Sciences, Biological Sciences) as well as notes from various scientific unions, their committees, commissions and permanent services on present activities. A calendar of meetings during 1964 is included. The *Year-book of the International Council of Scientific Unions, 1964*, besides the Calendar of Meetings for 1964, the lists of members of the Executive Committee, Council, and of the various Committees, and Commissions and Executive Bodies of the Permanent Services, includes the statutes and rules of procedure of the Council, and the rules for scientific and special committees and their charters (Rome: International Council of Scientific Unions, 1964). Relations of the International Council with the United Nations Educational, Scientific and Cultural Organization, the World Meteorological Organization, etc., are outlined and, besides a list of addresses of international organizations, there is an alphabetical list of members of the Executive Committee, scientific and special committees, the Council, and officers of the Scientific Unions.

Polish Science Publications

THE *Quarterly Review of Scientific Publications* (No. 1; 1964), issued by the Polish Academy of Sciences, now covers all scientific books published in Poland. There are 439 entries arranged under headings: general; social sciences; biological sciences; pure and technical sciences. There is an index of authors and a subject index.

The *Review of the Polish Academy of Sciences* for January–March (9, No. 1; 1964) includes articles by S. Huechel on the development of research on soil mechanics in Poland, and by J. Dylik on peri-glacial investigations and their significance for palæogeography, as well as an account by P. Kubchowski of the history, development and activities of the Institute of Drugs.

Polish Scientific Periodicals, which will appear ten times a year, and of which Nos. 1 and 2, 1964, have now been published, lists the contents of periodicals published in Poland, arranged under social sciences, biological sciences, pure and technical sciences, and includes an author index. The publication is available from the Polish Academy of Sciences, Palace of Culture and Sciences, Warsaw.

Land Resources in Australia

THE identification of distinctive environments and the pattern of their occurrence are the principal tasks of the Commonwealth Scientific and Industrial Research Organization Division of Land Research and Regional Survey, and the annual report for 1962–63 presents a review of the activities in progress (Pp. 73. Canberra: Division of Land Research and Regional Survey, C.S.I.R.O., 1963). The Land Resources Group has been engaged since 1946 in reconnaissance surveys of large areas, land systems being described to provide basic data for possible land use; productive land use for specific environments is the objective of the Biology Groups; the overall appraisal of the situation with respect to possible commercial production is made by the Agricultural Assessment Group. There is close co-operation throughout with other divisions of the Commonwealth Scientific and Industrial Research Organization. Most of the field work has been carried out in Northern Australia and Papua–New Guinea, with research stations in Northern Territory at Katherine, for crops suitable for monsoon conditions; at Darwin, for rice with seasonal flooding; at Alice Springs, for the problems of arid country; and in Western Australia at Kimberley, for irrigation investigations. Pasture management and the performance of tropical cross-bred cattle, peanut cultivation, selection of cotton varieties and cropping systems with oil seeds, and fluctuations in productivity resulting from erratic distribution of rainfall, are some of the problems under investigation. Water is obviously a dominant factor, and the work is supported by flexibly constituted research units concerned with plant–soil–climate relationships, investigations being directed, for example, to questions of stomatal behaviour in transpiration, transpiration suppressants, diurnal energy and water exchange, nutrient responses, and harmonic analysis of rainfall data. Environmental limitations inevitably impose restrictions on agricultural potential, and the information being collected will be invaluable.

Forest Products Research

THE Forest Products Research Laboratory has compiled a list of its publications which can be obtained free of charge on application to the Laboratory. The list consists of a selection of abstracts of papers published by Laboratory staff during the past few years together with a few Laboratory reports of which stocks of reprints are still available. Topics covered by the reports include: seasoning; woodworking; strength; protections of timber from fungal and insect attack; composite wood; chemistry; general and miscellaneous; industrial surveys. Copies of the list are available from the Director, Forest Products Research Laboratory, Princes Risborough, Aylesbury, Bucks.

Wind and Locust Migration

AN understanding of the factors which determine the course of locust migrations is becoming increasingly important, not only for the purpose of predicting which areas are likely to be invaded but also in order to make the most effective use of aircraft in the application of insecticides. *Meteorology and the Migration of Desert Locusts: Applications of Synoptic Meteorology in Locust Control*, by R. C. Rainey, is an exhaustive technical study of the applications of synoptic meteorology in locust control (*World Meteorological Organization. Technical Note No. 54.* (WMO No. 138. TP. 64. Anti-Locust Memoir 7.) Pp. v+115+3 plates. Geneva: World Meteorological Organization; London: Anti-Locust Research Centre, 1964. 25 Sw. fr.; 42*s*.). Hour-to-hour displacements of individual swarms have been recorded from the air. The direction of displacement follows closely the direction of the winds at swarm level. They may show a steady progressive displacement or there may be repeated reversals, sometimes resulting in closed loops. This down-wind displacement can lead to convergence of swarms or dispersal. A sound basis is thus provided for the use of current synoptic charts and of meso-scale meteorological observations in the interpretation and in the short-term forecasting of the movements of the desert locust.

Radiation Nephritis

DR. JOHN G. MAIER, of the Walter Reed Army Institute of Research, and Dr. George W. Casarett, of the University of Rochester, New York, have investigated the effects of single-exposure localized irradiation of the kidneys in beagle dogs at 500, 1,000 and 2,000 rads, using 220-kV X-rays (*Transactions of the New York Academy of Sciences*, Serial 2, 26, No. 5; March 1964). Both functional and morphological parameters have been investigated in animals killed six months after irradiation. One or both kidneys have been irradiated *in situ*, and single kidneys have been exteriorized and irradiated. From these and earlier experiments, it is concluded that irradiation of the canine kidney produces a progressive arteriolonephrosclerosis. The degree and rate of progression are related to the absorbed dose. At six months following irradiation, minimal arteriolonephrosclerotic changes were seen in the dog kidney receiving 500 rads, severe changes at 2,000 rads, and intermediate changes at 1,000 rads.

Harkness Fellowships of the Commonwealth Fund—New York

THIRTY Harkness fellowships of the Commonwealth Fund–New York are offered each year for study and travel in the United States. Candidates must be British subjects who are citizens of the United Kingdom and present Colonies by birth or by naturalization. Candidates should be between 21 and 32 years of age on September 1, 1965. Recent graduates and graduands who expect to receive their first degree in 1965 may apply, if they do not intend an academic career. Graduates proposing an academic career should have experience of postgraduate research. Other candidates, including non-graduates, should produce evidence of professional qualifications or considerable practical experience. The fellowships are tenable for between twelve and twenty-one months. Round-trip passages to the United States are provided. Emoluments include living and family allowances, travel in the United States, tuition and research expenses, and allowances. Selection of Fellows for nomination to the

Fund is in the sole discretion of the Committee of Award, which will conduct interviews at Harkness House, London, in March 1965. Further information and details of the fellowships can be obtained from the Warden, Harkness House, 38 Upper Brook Street, London, W.1. Applications, on forms provided by the Fund, must reach Harkness House before November 12.

The Paul Instrument Fund Award

THE Paul Instrument Fund Committee has made grants as follows: £1,100 to Dr. P. B. Hirsch, lecturer in physics in the University of Cambridge, as a supplementary grant, for continuation of his work on an electron microscope with velocity analyser. £5,400 to Prof. D. J. E. Ingram, professor of physics, University of Keele, for the design and construction of a millimetre wave-length electron resonance spectrometer to work at zero or near zero magnetic field strengths and with as wide a frequency coverage as possible. £2,200 per annum for two years to Dr. H. Motz, Donald Pollock reader in engineering, University of Oxford, for the construction of a pulsed millimetre wave generator. £3,400 to Dr. E. E. Schneider, reader in solid-state physics, University of Newcastle upon Tyne, as a supplementary grant, for continuation of his work on the application of superconducting cavities to magnetic resonance spectrometers. The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Institute of Physics and the Physical Society and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

The Australian Association of Clinical Biochemists

THE following have been elected officers of the Australian Association of Clinical Biochemists for the year 1964–65: *President*, Dr. W. Roman; *Secretary*, Dr. D. H. Curnow; *Treasurer*, Dr. D. Watson; *State Representatives on Council*, Mr. M. J. Thomas (Queensland); Dr. F. J. Radcliff (New South Wales); Dr. J. Mackenzie (Victoria); Mr. Z. A. Mejglo (Tasmania); Dr. R. I. Cox (South Australia); and Dr. S. S. Alexander (West Australia).

Institute of Applied Science of Victoria

THE annual report for 1962–63 of the Institute of Applied Science of Victoria records that the new name, "Institute of Applied Science", bestowed by an Act of Parliament in 1961, may now be seen across the outside entablature of the building (Pp. 22. Melbourne: Institute of Applied Science of Victoria, 1964). The post-war years have witnessed the metamorphosis of the original Industrial and Technological Museum into an establishment which now includes a planetarium, a radiocarbon-dating laboratory, evening astronomical telescope demonstrations, special school services, and a fresh approach to applied science display. A large diorama illustrates the Yallourn open-cut works for coal and shows the overburden stratum and various working levels. The model also includes a 1,200-ton coal-winning dredge, belt conveyor, water-spray reticulation, etc. Another display given by Qantas Empire Airways deals with aeroplane engines and summarizes progress from the Wright brothers to turbo-props and turbo-jet propulsion.

University News: London

DR. E. A. BEVAN, University lecturer and demonstrator in the University of Oxford, has been appointed to the chair of botany at Queen Mary College. Dr. James Green, lecturer at Bedford College, has been appointed to the readership in zoology at Westfield College. The following titles have been conferred: professor of sociology (with special reference to the Far East), on Mr. R. P. Dore in respect of his post at the London School of Economics and Political Science and the School of Oriental and African Studies; professor of plant chemistry, on Dr. L. Fowden in respect of his post at University College; professor of geography, on Dr. R. J. Harrison-Church in respect of his post at the London School of Economics and Political Science; reader in geography, on Dr. K. M. Clayton in respect of his post at the London School of Economics and Political Science, and on Dr. J. T. Coppock in respect of his post at University College; reader in chemistry, on Dr. A. G. Davies in respect of his post at University College; reader in forensic psychiatry, on Dr. T. C. N. Gibbens in respect of his post at the Institute of Psychiatry; reader in comparative education, on Dr. B. Holmes in respect of his post at the Institute of Education.

Announcements

THE autumn meeting of the Society for Water Treatment and Examination will be held at Llandudno during September 30–October 2. Further information can be obtained from A. W. H. McCanlis, 41 Carshalton Road, Sutton, Surrey.

A SYMPOSIUM on "Major Elements in Nutrition", organized by the Scottish Group of the Nutrition Society, will be held in Dundee on September 12. Further information can be obtained from Dr. C. F. Mills, Rowett Research Institute, Bucksburn, Aberdeen.

A MEETING of the Biochemical Society will be held in the University of Cambridge during September 17–18. Further information can be obtained from Dr. H. R. V. Arnstein, National Institute for Medical Research, The Ridgeway, Mill Hill, London, N.W.7.

A SYMPOSIUM on "The Problems of Food Additives", organized by the Royal Institute of Chemistry, will be held in Manchester on October 1. Further information can be obtained from H. H. Armstrong, Stockport College for Further Education, Wellington Road South, Stockport.

A SUMMER school in "Organic Spectroscopy", arranged by the Royal Institute of Chemistry in collaboration with the Society for Analytical Chemistry, will be held in the University of London School of Pharmacy during September 6–12. Further information can be obtained from D. G. Chisman, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

THE fifth international Machine Tool Design and Research Conference will be held in the University of Birmingham during September 14–18. The Conference will include sessions on: international collaboration on machine tool chatter research sponsored by the U.S. Air Force; machine tool design; high-energy rate forming; metal cutting; explosive forming; metal forming; recent developments in machine tool technology. Further information can be obtained from the Organizing Secretary, Department of Mechanical Engineering, University of Birmingham, Edgbaston, Birmingham 15.

THE eighth Conference on Analytical Chemistry in Nuclear Technology on "The Determination of Interstitials and Trace Constituents in Reactor Materials and Products", sponsored by the Analytical Chemistry Division of Oak Ridge National Laboratory, will be held in Gatlinburg, Tennessee, during October 6–8. The Conference will include sessions on: spectrochemical and X-ray methods of analysis; mass spectrometric methods of analysis; nuclear methods of analysis; gas chromatographic methods of analysis; determination of carbon, hydrogen, oxygen and nitrogen in metals; determination of trace constituents by diverse methods. Further information can be obtained from C. D. Susano, Oak Ridge National Laboratory, P.O. Box X, Oak Ridge, Tennessee, 37831.

GOVERNMENT EXPENDITURE ON SCIENTIFIC RESEARCH, 1963

THE report of the Council for Scientific and Industrial Research for the year 1963* records gross expenditure during the year ended December 31, 1963, of £19,479,540, compared with £16,691,172 in the year ended March 31, 1962. The 1963 figure is reduced to £17,231,547 by various receipts from industry and other sources for services rendered, of which £960,142 was from other Government departments and £977,482 from industry—£224,085 being received by the National Physical Laboratory. The net increase on 1962 was £2,853,345, while staff rose from 6,525 to 6,723 during the calendar year. Grants for special researches again rose, to £3,297,186 compared with £2,275,060 in 1962, contributions to the European Organization for Nuclear Research from £1,359,000 to £1,700,000, and receipts of £116,196 reduced the subscriptions to the North Atlantic Treaty Organization and Organization for European Economic Co-operation scientific schemes to £76,436. There is a new item of £28,827 for United Kingdom Space Research Management Services.

Postgraduate training awards amounted to £1,735,067 (£1,289,903 in 1962), and the 1,958 new studentships, an increase of 22 per cent, brought the total current at the end of the year to 4,036. While the value of research fellowships was increased by £100, only 78 new awards were made, compared with 92 in 1962, bringing the total current to 147. Besides 38 studentships and 18 fellowships awarded for study abroad (24 and 28, respectively, in 1962), 20 fellowships and 1 studentship were awarded to assist British scientists and engineers to return from North America. Of the 3,469 current research studentships, 461 were in biology and biological chemistry, 264 in chemical engineering and metallurgy, 979 in chemistry, 161 in electrical and 291 in other fields of engineering, 238 in geology, 76 in the human sciences, 296 in mathematics and 703 in physics. The advanced course studentships were distributed mainly in mathematics (115), physics (91) and engineering, other than electrical (85), with 47 in the human sciences, 44 in chemical engineering and metallurgy, 36 in electrical engineering, 26 in geology, 25 in biology and biochemistry, and 21 in chemistry. All 77 first-year studentships were again in chemistry, and of the 147 research fellowships, 55 were in chemistry, 40 in physics, 25 in biology and biochemistry, and 10 in geology.

Grants for special researches totalled 929, 587 being new, and of the 929 totalling £11,813,668 in value in the year ended March 31, 1963, 194 (valued at £1,308,893) were in chemistry; 149 (£1,334,205) in technology; 147 (£947,245) in biology; 115 (£955,525) in physics; 72 (£601,677) in geology; 66 (£466,881) in the human sciences; 64 (£645,358) in metallurgy and materials; 51 (£3,008,060) in nuclear physics; 33 (£596,668) in space research; 19 (£1,073,275) in astronomy; 9 (£47,311) in mathematics; five each in documentation and in reactors totalled £50,850 and £777,720, respectively. During the academic year 1962–63, the Research Grants Committee considered 639 new applications for grants with a total value of £6,318,000, compared with 487 valued at £4,147,000 in the previous year, and made 513 grants with a total value of £3,596,000 (excluding grants of £100,000 for maintaining existing capital projects, compared with 390 amounting to £2,313,000 in the previous year. The Human Sciences Committee made 31 awards amounting to £150,000. In addition, a grant of £1·1 million was approved for the construction and operation of a 100-MeV electron linear accelerator to enable Prof. P. I. Dee to carry out an extensive programme of investigation into photo-problems in nuclear physics (the accelerator is being built in the grounds of the National Engineering Laboratory, East Kilbride). A further grant of £139,000 was made to the University of Manchester to enable Sir Bernard Lovell to make a survey of the angular diameter of radio stars. A grant of £121,500 was made for Prof. N. J. Petch's work at the University of Newcastle upon Tyne on the development of materials with improved resistance to brittle fracture; smaller grants for work in this field, totalling £126,082, were allocated to other universities. An earmarked grant of £15,300 was offered to the British Welding Association, £100,000 for staff and running costs until 1967 for fundamental research in biosynthetic mechanisms under Prof. E. B. Chain at the Imperial College of Science and Technology, and £142,000 to the University of Southampton to assist the establishment of an Institute of Sound and Vibration Research under Prof. E. J. Richards.

With the exception of fire research and hydraulics research, in which net expenditure decreased slightly, from £57,056 to £39,668 and from £118,152 to £105,489, respectively, expenditure on all branches of the Department's work increased during the year, and in these two fields receipts amounting to £130,937 and £161,379 (both up in 1962) accounted for more than half the gross expenditure. Likewise, a decrease in the net expenditure of the National Lending Library for Science and Technology from £258,922 to £248,024 is accounted for by an increase in receipts from £45,327 to £87,803. While receipts of £399,472 in the previous year gave expenditure on the Tropical Products Institute a credit balance of £169,721, this year they fell to £212,965, leaving the net expenditure at £17,472. There is a new item of £53,215 net on development contracts. The major increases in expenditure during the year are the National Physical Laboratory (£2,164,502 gross; £2,033,109 in 1961–62); road research (£1,086,674; £970,403); the Warren Spring Laboratory (£538,554; £471,181); the National Engineering Laboratory (£1,006,609; £924,978); building research (£858,271; £781,037); radio research (£379,041; £320,163); and the National Chemical Laboratory (£431,416; £409,887). For forest products research the corresponding figures are £216,682 and £194,619; Geological Survey and Museums, £649,807 and £578,919; Laboratory of the Government Chemist, £524,375 and £491,215; Torry Research Station, £252,709 and £226,696; water pollution research, £199,932 and £183,550. Expenditure on headquarters administration increased from £615,536 to £678,775, annual grants to research associations from £2,005,453 to £2,073,565, and special assistance to industry from £59,675 to £81,209.

A FUTURE FOR BRITAIN'S WATERWAYS

IN a written answer in the House of Commons on July 31, 1963, the Minister of Transport, Mr. E. Marples, indicated that he expected a preliminary report from the British Waterways Board on its general views as to the future use of the inland waterways, for which it is responsible, about the end of that year. This interim report was issued on December 12, 1963, and published on January 30, 1964*.

While the report emphasizes that the views offered are only provisional, the general approach to new policy outlined is of wide interest. The views raised will need testing by systematic financial investigation not only of the multi-user policy, which the Board now proposes, but also of other courses open to them, as well as by engineering investigations. Interest in the waterways has, however, been accentuated since the report appeared by the growing importance of multi-user approach in other fields, as is to be seen, for example, in the Buchanan Report on road transport (*Nature*, 201, 1059; 1964), in the Manchester proposals for water supply (*Nature*, 202, 1; 1964), and in the proposed scheme for a barrage across Morecambe Bay (*Nature*, 203, 125, 219; 1964). Incidentally, it should be noted that in writing the report, the Board—which was set up by the Transport Act, 1962, and took over the administration of the waterways from the British Transport Commission on January 1, 1963—was by no means clear as to what the impact of the Water Resources Act of 1963 would be on its own function for the supply and distribution of water in England and Wales, or ultimately on water prices.

The report begins by making clear just how far the responsibilities of the Board extend, for there are many inland waterways besides the 2,000 miles vested in the Board, including, as well as the Thames and many rivers, the Manchester Ship Canal (including the Bridgwater Canal), the Rochdale Canal and the Exeter Canal. Those for which the Board is responsible are mainly in England, but they include the Caledonian and four other canals in Scotland, and the Monmouthshire and Brecon Canal and two others in Wales, and before nationalization nearly half of them had been owned or controlled by railway companies. Furthermore, they differed widely in their width, their state of maintenance, and the extent of their use for commercial or other traffic or for other purposes; some 500 miles had been formally closed to traffic, while of a further 600 miles no longer used by commercial traffic some had become unnavigable wholly or in part.

The Board is required, under Section 10 of the Transport Act, 1962: (1) to provide, to such extent as it thinks expedient, services and facilities on these inland waterways and port facilities at any harbour owned or managed by it, having due regard to efficiency, economy and safety in the services provided; (2) to review the manner in which the inland waterways owned or managed by it may be put to the best use, to formulate proposals to that end, and to take all steps open to it to achieve that object. Financially, Section 18 requires the Board to ensure that revenue is sufficient to meet charges properly made to revenue, taking one year with another. Besides the actual waterways, the Board took over responsibility for nearly 100 reservoirs, various docks and warehouses, some estate property, repair yards and workshops, some fleets of carrying craft and some hire-pleasure craft.

This interim report represents the results of the Board's first examination of all aspects of the future use of the inland waterways for which it is responsible, both from the point of view of commercial transport and all the other varied purposes which the waterways could serve. Already the Board is clear that radical departure is necessary from the recommendations of the Bowes Committee of 1956—although the report of that Committee contained pointers to a new and more positive policy. The Board has already completed its appraisal of management organization of the waterways and is altering the general shape and structure of that organization, replacing the geographical divisions by functional divisions, with two Regional Centres, one at Gloucester and one at Leeds, for certain operational purposes. While these changes, to be completed by December 1965, are not expected to cause any significant redundancy among the present 4,000 staff, the Board believes that the new structure will provide the essentials of a sound long-term basis for managing the undertaking and will thus encourage both the present staff and future recruits to make British Waterways their career. In Scotland, while the Caledonian Canal will continue to be run by a manager who will be responsible to the four functional Headquarters officers for those respective aspects of his work and who will utilize the appropriate Headquarters departments for specialized skills for which it would be uneconomic to provide separately, the other canals will for engineering matters be made into one engineering area, with an area engineer reporting direct to the chief engineer.

Before outlining its first general views on policy, the Board directs attention to some basic factors in the financial situation. On present information, maintenance and running costs of a waterway for major transport use are several thousand pounds sterling a mile per annum, but only some £700–£1,400 a mile for canals used mainly by pleasure craft. Here, however, there is need to examine imaginatively the possibilities of savings by new approaches to maintenance which would not lead to long-term deterioration. Conversion of these canals for use mainly as water channels would offer a further saving of 15–20 per cent, and perhaps another 10 per cent saving might be possible if such canals could be reduced to 'mere existence' standards. The true cost of elimination is not accurately known, but is expected to be about £5,000 a mile, with no offsetting income, although maintenance would be saved.

It is against this background that the Board has formed its present opinion that the most workable and defensible basis for future policy is a positive one of cohesion and development of the waterways as an organized entity in the light of all present social and economic conditions. A unified and economical administration should be set up with the prime object of maintaining them for all possible transport and related uses, and also for any and every useful public purpose appropriate to them. Moreover, it should endeavour to make them pay their way as a whole and to the maximum possible extent, by every feasible method of cost recovery, charges and voluntary contributions. The Board believes that it is possible to make them pay much better than in the past when sectional pressures were responsible for some canals being deliberately allowed to fall into disuse and neglect. It regards a policy of run-down and closure as wasteful, frustrating and inefficient, while the third alternative of dismemberment is likely to lead to a long period of uncertainty about individual waterways, in which their condition and prospects would deteriorate, and ultimately to a more expensive and less efficient structure.

---

* British Waterways Board. *The Future of the Waterways: Interim Report of the Board.* Pp. vii+52. (London: H.M.S.O., 1964.) 7s. 6d.

The need for early decision is reiterated throughout the report and is one factor responsible for the issue of an interim statement. Particularly in respect of some special cases, such as the Kennet and Avon Canal, the Leeds and Liverpool Canal and the main line of the Grand Union Canal, and some of those used for pleasure craft, the Board stresses the need to provide some reasonable assurance of continuity. The development and use of waterways have for generations been hindered by uncertainty about their future, and this prolonged uncertainty has exacerbated the very difficulties which caused it in the first place. The Waterways Board fully endorses the observations of the Bowes Committee on this point, and this applies to almost every field of the future activity of the waterways.

The Board argues very cogently that this policy of multi-user is the most rational and efficient policy, and it points out that the undertaking for which it has assumed responsibility cannot, as a whole, any longer be regarded solely as a national transport system. As such, some of it is manifestly out of date, though it might well be asked whether the practicability has been sufficiently carefully considered of developing even some sections of the waterways as an alternative means of relieving the congested road system of some of the heavy traffic responsible for delays and damage, or to fill the gaps left by some of the closures of railway lines that have already been made or are in prospect. That, of course, properly lies outside the special responsibility of the Board, but once again it indicates the real danger of departmentalism which the handling so far of the Robbins Report and the Buchanan Report has demonstrated. Apart from that, however, the interim report on the future of the waterways shows clearly the impracticability of neatly and separately arranging waterways as usable and unusable for transport, or even separately labelling individual waters for single particular purposes.

All this is admirably shown on the excellent series of charts with which the report is illustrated. Although, as has already been emphasized, the Board is careful to insist that its present views are subject to modification, the imaginative and constructive approaches it displays in its considerations of commercial transport and related activities, of water supply and channelling, and of the use of the waterways by pleasure craft, for cruising, angling and other purposes are some of the most encouraging and helpful features of the report. There is, for example, the comment that a reasonable transport diversity is a useful support to a healthy economy. Again, the Board notes that many waterways could without major expansion cater for more traffic than they do at the moment—the Lea, going through the industrial East End and the City to the London docks, is one example. It is clear that, given the reasonable support on which it should be able to count, the Board will be prepared to consider in due course with real vision the possibilities of major expansion or improvement or even the building of new waterways.

What does emerge from this interim report is that Britain now has a Waterways Board with a positive policy and one which is imaginatively alive to the many possibilities which such a policy holds for various aspects of public welfare, including the intelligent conservation and use of water resources. Although the revenue for angling is minute compared with the cost of maintaining waterways, that does not mean that angling will be disregarded by the Board, and it recognizes the complexity of the statutory position and is prepared to reconsider this in due course. Meanwhile, in a situation in which the annual rate of loss has been reduced from £1·3 million to less than £1 million and could be reduced by a further £0·75 million if all went well, the Board is concentrating on the general concept of the multi-user system as the best opportunity of attracting new revenue. It is indeed also required by the Transport Act of 1962 to pay interest on a commencing debt, estimated at £19·2 million, retention of which is scarcely a stimulus to sound financial management. Nevertheless, while the Board is not yet ready to make firm proposals regarding the future treatment of this debt, it hopes to do so later. How the engineering survey and the systematic financial and costing investigations to be put in train will affect the tentative views expressed in this report has yet to be seen. It can at least be added, on the evidence of this report, that if the British Waterways Board does not, within the next few years, provide Britain with a waterways system which measures up to the opportunities displayed in this report with insight as well as realism, the responsibility is likely to be that of the Government, and particularly the Minister of Transport, for failing to support it. After this report, the Minister of Transport can have no excuse if he fails to deal urgently and constructively with the problems of administration involved at the central as well as at the regional level when problems have to be handled from the point of view of numerous functions and services, far transcending local, and sometimes regional, needs and interests.

DISEASES OF THE HOP

COMMUNICATION between biologists in different countries, working in different physical and intellectual environments, and publishing their results in different languages, is perhaps nowhere more difficult than in the field of plant virus diseases; the basis for identification of the causal agent still depends on the description of variable and often transient symptoms in one or more species or varieties of host plants, even though these diagnostic techniques are being increasingly supplemented by data from the electron-microscope and the ultracentrifuge, and from serological investigations. Much can be gained by assembling an international group of specialists for a working conference to see and handle diseased material and to discuss common problems. This can be especially valuable if the proceedings of the conference are not published in detail and the participants can therefore feel free to speculate. The conference on hop diseases, sponsored by the East Malling Research Station with the Hop Research Department of Wye College, and held during June 29–July 2 at East Malling and Wye, was organized on this basis. The incentive for arranging the conference came initially from virus workers; but the programme also included discussions on the major fungal diseases of the hop.

The first day of the conference, under the chairmanship of D. Rudd Jones (Agricultural Research Council, U.K.), was devoted entirely to virus diseases. Only one virus, hop mosaic, appears to be recognized in all the major hop-growing areas of the world, though it is not clear how much variation there is between strains of the virus. Papers on this disease dealt with its effect on the yield and quality of early and late cluster hop varieties (C. B. Skotland, U.S.A.) and with changes induced by the virus in the mineral content of the leaves (R. Marocke, France).

Kräuselkrankheit (crinkle) is a disease of economic importance in Germany and eastern Europe, but it is not recognized elsewhere. Its symptomatology and control in Czechoslovakia were discussed by J. Kriz (Czechoslovakia); and P. Chrometzka (Germany) showed how various climatic and nutritional conditions could lead to masking of the symptoms. A striking feature of the disease is the effectiveness with which symptoms can be eliminated by treating affected plants with zinc salts or zinc-containing fungicides; this, together with the somewhat equivocal results of attempts to transmit the disease by grafting, suggests the possibility that zinc deficiency is directly involved.

Kräuselkrankheit symptoms have a number of features in common with those of nettlehead. A paper on the ætiology of this disease by J. T. Legg (U.K.) was presented by K. R. Bock (U.K.), the author being at present in Ghana. This paper also dealt with hop line pattern virus, which can be latent in many varieties but which, when present, either facilitates infection with nettlehead virus or contributes to the development of the nettlehead syndrome. Nettlehead is not recognized in continental Europe, but is probably present in the United States.

Kräuselkrankheit is probably not synonymous with nettlehead; some evidence for this was mentioned in the text of a paper by H. E. Schmidt (D.D.R.). Unfortunately, no member of this author's laboratory, the Institut für Phytopathologie at Aschersleben, was able to attend the conference, and it was not possible to discuss in detail what appeared to be an important contribution to diagnostic procedures for hop viruses. For example, a number of herbaceous indicator plants have been used at Aschersleben to differentiate strains of 'hop ring-and-banding-mosaic virus'. It was not possible to determine whether this virus is related to the hop line pattern virus described by Legg; the latter virus has not been recognized in Germany, Czechoslovakia or Yugoslavia, but is believed to be present in the United States.

Herbaceous indicators have also been used by D. H. Hall (U.S.A.) during investigations of a yellow leaf blotch virus of hops in California, a disease that seems to resemble one previously reported from New Zealand, but is apparently not recognized elsewhere.

Infectious sterility is recognized only in eastern continental Europe. It was discussed by J. Kriz, who indicated that control was likely to be achieved in the near future by the propagation of selected virus-free clones. This preventive approach to the control of virus diseases in general was also stressed in contributions to the discussion by delegates from western continental Europe, Britain and the United States, whereas in southern Germany the curative approach by treatments aimed at ameliorating the effects of the disease on the host plant is predominant.

Split leaf blotch, a disease well known in Britain, is possibly present in Europe and almost certainly present in the United States.

In the second session, under the chairmanship of W. G. Keyworth (U.K.), discussions on hop *Verticillium* wilt diseases were opened by G. W. F. Sewell (U.K.), P. W. Talboys (U.K.) and T. Christie (New Zealand).

The taxonomic position taken by most British workers is that the 'Dauermycelien' and 'microsclerotial' forms of *Verticillium* are referable to the two species *V. albo-atrum* and *V. dahliae*, respectively. Though a majority of American pathologists have regarded these as different forms of *V. albo-atrum*, an increasing number of them are accepting the division into two species as a matter of convenience if not always of conviction.

The major wilt pathogen of hops in Britain and Germany is *V. albo-atrum*, and limited outbreaks caused by this species have also occurred in New Zealand. In the United States relatively minor outbreaks in the past have been caused by *V. dahliae*; but C. E. Horner reported that a new occurrence of the disease in 1964 was caused by *V. albo-atrum*. In other countries hop wilt is of no economic significance and in most areas has not been reported.

The virulent strain of the pathogen causing progressive wilt in Britain does not seem to occur elsewhere, though tests carried out in Germany and New Zealand to discover whether the strains present there correspond with those causing progressive and fluctuating wilt in Britain are difficult to assess because the techniques and environmental conditions of the trials were different from those in Britain. The marked response of *Verticillium* wilts to environmental conditions is an important factor to be considered in investigations both of resistance in the host and of virulence in the parasite. Thus, the initial development of the wilt problem in Germany, and the variable incidence of acute disease from year to year in moderately resistant varieties on certain sites in Britain, were both ascribed, at least in part, to low temperatures during the summer. The increasing prevalence of *V. dahliae* as a wilt pathogen in warmer climates is another aspect of the same problem.

Present investigations of the host–parasite relationship in England continue to lay stress on the importance of the extra-vascular root tissues in determining the severity of the disease.

Research on the status of *V. albo-atrum* in the soil indicates that infection of roots of dicotyledonous plants provides an important means of maintaining soil populations of the pathogen, whereas under a pure grass sward this organism is rapidly eliminated. *V. dahliae*, however, is apparently not amenable to this method of control.

Discussions on downy mildew (*Pseudoperonospora humuli*) fully occupied the third day under the chairmanship of J. E. Crosse (U.K.). The meeting was held at Wye College, and papers were presented by F. Zattler (Germany), J. M. Ogawa (U.S.A.), J. R. Coley-Smith (U.K.), C. E. Horner (U.S.A.), Y. Mori (Japan) and L. Vent on behalf of Z. Petrlik (Czechoslovakia).

Most of the discussion during this session was concerned with over-wintering of hop downy mildew and with the value of streptomycin in early-season control of the disease. In Great Britain, the United States and Japan there is now a great deal of evidence to show that downy mildew over-winters mainly as mycelium in infected hop rootstocks. Oospores of the fungus are very rare in the United States, and although of common occurrence in Britain have never been observed to germinate. On the continent of Europe it is still widely believed that spring infections arise from oospores, and there is certainly evidence that infection of hop rootstocks is less common there than in Britain or the United States.

There was disagreement about the value of streptomycin for early-season control of hop downy mildew. Good control has been achieved in certain areas of the United States but not in others. In Great Britain the antibiotic appears to give slightly better results than conventional protectant fungicides. Mixed results have been obtained in Japan, but in Western Germany the antibiotic has given very poor results.

Control of downy mildew by the use of resistant hop varieties has not reached an advanced stage, except in Western Germany, where two new resistant varieties have been distributed to growers. There is no information regarding physiological specialization in *Pseudoperonospora humuli*, but there appear to be differences in the susceptibility to downy mildew of certain commercial varieties in different countries, and the possibility of physiological specialization should therefore be borne in mind when breeding for disease resistance.

On the final day, with A. F. Posnette (U.K.) in the chair, there were short discussions on miscellaneous diseases, including powdery mildew (*Sphaerotheca humuli*), canker (*Gibberella pulicaris*), *Botrytis* infection of cones, a heptachlor-induced die-out of hop crowns in Washington State, and *Phytophthora* rots in New Zealand and Britain.

The conference was supported by the Agricultural Research Council and the Hops Marketing Board.

P. W. TALBOYS

ARTHRODIRAN ANATOMY

THE classification used by E. Stensiö in his recently published *Anatomical Studies on the Arthrodiran Head*[*] differs from that in present-day text-books. Stensiö, like Jarvik, joins the Placodermata with the Elasmobranchii in a class "Elasmobranchiomorphi". The Placodermata contain the super orders Arthrodira and Holocephali, the former including Gross's Euarthrodira (Arthrodira of Woodward) and the Antiarchi. Stensiö is in agreement with the cogent arguments of Ørvig for relating the Euarthrodiran order of Ptyctodontids with the modern Chimæras—"everything decidedly goes to prove that the Holocephalans are derived from early primitive Ptyctodontids and consequently in all probability are the last survivors of the Arthrodiran stock". Evidently, many general zoologists and palæontologists will be referring to this work to decide how far these opinions are now to be followed.

The figures and plates of Part 1 are excellently set out and there are many beautiful colour-figures. These, the work of a great authority, writing on his subject, enable a more complete picture of the Euarthrodiran fish to be formed. But in the reconstructions, based largely on 'serial grindings', comparison is made predominantly with the cranial anatomy of modern Elasmobranchs rather than with that of Acanthodians, Holocephalans, or early Elasmobranchs: this procedure begs the question of whether the Elasmobranchs are so closely related to the Arthrodires as Stensiö believes. Certainly it is difficult to accept that these early fishes were so advanced as they appear here, for example, in the relations of the profundus nerve to the rest of the trigeminal complex.

The systematic arrangement of the orders is based on the author's views on the evolution of the Arthrodiran pectoral fin, although the Dolichothoraci are treated first in the text. Should these views eventually prove to be mistaken, this would detract little from the value of the book. But many special features of the Arthrodires, such as the strange and probably primitive arrangement of the pineal system, and the evolution, apparently, of autostylic jaw-suspensions from a hyostylic one, really need authoritative explanatory diagrams rather than extensive verbal descriptions. Presumably these will be provided in Part 2, which will cover nine orders, including the crucial Ptyctodontids, and a summary. Part 1 lacks a separate index, so on all counts it is to be hoped that Part 2 will appear soon.

INSPECTION OF ALKALI, ETC., WORKS

THE one hundredth report on alkali, etc., works in England and Wales for 1963, issued by the Chief Inspector[*], covers the centenary year of the Alkali Act. An interesting feature of the report is the brief account appended of the early history of the Act and of the Inspectorate. At the end of the year, 2,061 works were registered under the Act involving operation of 3,331, but the number of registered works was 16 fewer than at the end of 1962, and 152 fewer than at the end of 1959.

The Chief Inspector points out that it is often small works, unsuitably placed and surrounded by dwelling-houses, which take up a disproportionately large amount of the time of the Inspectorate, and neither the number of works nor the scheduled processes registered, nor the national statistics for production, can alone provide a yard-stick for the hazards.

During the year, 10,850 visits were paid, including 135 special visits by the Chief or Deputy Chief Inspector, of which 244 were to, or in connexion with, works not registered under the Act, 43 being concerned with the control of radioactive emissions and 43 to, or in connexion with, colliery spoilbanks. During the inspections, 3,433 quantitative analyses were made of gases evolved from the processes, compared with 4,331 in 1962. The decreased number of tests is largely due to the absence of any need for special investigations at the older works. In addition, 615 special samples were taken and submitted for analysis by the Government Chemist.

The specific complaints investigated, largely at the request of the local authorities, concern some 323 works, 256 of which were registered under the Act. Complaints against registered works were most numerous against isotope works, ceramic and electricity works, iron and steel works, cement works, and aluminium works, the volume of complaints against the heavy chemical industry being small.

Commenting on the inclusion in the list of noxious or offensive gases under the control of the Inspectorate of compounds which cannot by any manner of means be held to be toxic, the Chief Inspector points out that toxicity is not the full criterion, and that there is the matter of general nuisance and of interference with amenities. The Chief Inspector also points out that the arrangements for visiting the establishments of the Atomic Energy Authority to consider the best practical means for reducing to a minimum the emission of radioactive gases, mists and dusts, and to make sure that any such discharges are regulated so that public health is in no way in danger, continue to operate adequately. Satisfactory standards continue to be maintained and no public health hazard has arisen. The same satisfactory system is being applied to the nuclear power stations of the Central Electricity Generating Board.

An interesting point noted regarding the cement-production works is that one of the main factors leading to high dust emission when using estuarine clay is the salt content. Moreover, the main alkali metal in the dust is not sodium but potassium, which seems to be present largely as potassium chloride and can at times be as much as half the emission.

Under the same cover is included the report of the Chief Inspector of Alkali, etc., Works (Scotland) for the same year. Under the Scottish Act 275 works operating 375 processes are registered, and some 444 visits were paid, including 44 joint and independent visits by the

Chief Inspector, of which about 146 visits were on work not falling directly within the provisions of the Act, but within those of other statutes relating to the prevention of air pollution. The experimental programme of testing dust emissions yielded more useful information in the 30 tests made during the year, but it was again apparent that full observance of the recommended procedure for testing was scarcely practical at most works, although close approximations were made wherever possible. Another markedly defective electrostatic precipitator was found, and again its performance was not suspect by an external instrumental indication of its operation.

To this report also is appended a brief historical account, this time dealing with the operation of the Alkali Act in Scotland during the past hundred years.

BLAST-FURNACE CEMENT IN SOUTH AFRICA

MANY years ago it was established (in Germany) that certain slags, by-product of iron-ore smelting in blast-furnaces, if rapidly quenched from the molten state, then finely ground with an activator such as lime or Portland cement, would set and harden very much like ordinary Portland cement. This resulted in the development of a large cement industry in Europe based on waste slag, which, as a result of considerable research over the years, has greatly expanded in production and economic importance, especially in those countries concerned with an indigenous iron and steel industry.

In the case of South Africa there appears to be a basic difference between the available slag from the iron and steel industry compared with that used for cement-making elsewhere, in that the slag produced in the Republic has a much higher magnesia content than that normally used overseas. For some time cement technologists considered that the use of high magnesia slag was liable to lead to disruptive expansion in Portland cement products made from it; consequently this local slag was looked on with suspicion. However, with continuing expansion of the iron and steel industry and concomitant mounting of slag production (this is at present running at 1,200,000 tons per annum), something drastic had to be done to counteract the accumulation of this unwanted by-product. Research on the problem was initiated at the National Building Research Institute of the Council for Scientific and Industrial Research, Pretoria, and eventually it was demonstrated that this high-magnesia slag was not conducive to unsoundness and that, under prescribed conditions, a good-quality cement could be manufactured from it.

Writing in the *South African Review* (C.S.I.R., ref. No. *R/BOU* 108; 1963/64), Dr. N. Stutterheim, vice-president of the Council, briefly describes the events leading up to the now successful utilization of this slag. He says: "Discussions between the iron and steel industry, which had sponsored the research, the cement companies and the C.S.I.R , resulted in the manufacture of two types of cement: one an interground mixture of granulated slag and Portland cement clinker and the other a finely ground granulated slag which is then mixed with Portland cement in the concrete mixer on the construction site. . . . Last year about 350,000 tons of granulated slag was converted to cement; i.e., about 12 per cent of the country's cement requirements were met from this source. This is only 30 per cent of slag output whereas at least 80 per cent could be so utilized".

It is concluded that it has now been abundantly proved that it is economic to use South African slag for cement manufacture; that by so doing capital and running costs are saved; resources of limestone and coal, otherwise required for equivalent Portland cement production, are extended; a cement possessing properties similar to those of Portland cement, but at lower cost, is being extensively marketed; and it is in the national interest that increasing use be made of this waste slag for cement production.

H. B. MILNER

UPTAKE OF HYDROCARBON CARCINOGENS BY LYSOSOMES

By DR. A. C. ALLISON and DR. L. MALLUCCI[*]

National Institute for Medical Research, London, N.W.7

ALTHOUGH polybenzenoid hydrocarbon carcinogens have been intensively investigated since their discovery more than thirty years ago, remarkably little is known about their intracellular fate and the way by which they bring out malignant changes. In examining the localization of carcinogens, two main approaches have been used: histological examination of the fluorescence of treated tissues and chemical analysis of isolated cell constituents. The first technique has shown that, both *in vivo* and *in vitro*, hydrocarbon carcinogens are quickly taken up into small masses in the cytoplasm of cells and remain demonstrable there for several weeks[1-5]. The second approach has established that if careful fractionations are carried out the carcinogens are not found in nuclei or bound to nucleic acid but are present in cytoplasmic constituents, an appreciable proportion being bound to protein[6-8]. Whether hydrocarbon carcinogens become associated with particular cytoplasmic constituents has never been clear, and our experiments were undertaken to throw light on this problem.

Cell cultures. Cultures of four cell types were made on coverslips. Primary *Macaca* monkey kidney cell cultures were grown in Medium 199 (Glaxo) + 10 per cent calf serum inactivated by heating at 56° for 0·5 h. Chick embryo cell cultures were maintained in *tris*-(hydroxymethyl)-aminomethane–Gey's medium with peptone and lactalbumin hydrolysate[9]. HeLa cells were cultured in Medium 199 + 5 per cent inactivated calf serum. Macrophages were obtained without prior stimulation by intraperitoneal inoculation of 3 ml. of culture medium containing 10 I.U. of heparin per ml. into mice of strain *VSBS/NIMR* weighing 18–20 g. After brief massage the cells were gathered, washed and dispensed in tubes containing small coverslips. The culture medium was solution 199 + 20 per cent inactivated calf serum.

Carcinogens. Hydrocarbon carcinogens (9,10-dimethyl-1 : 2-benzanthracene (DMBA) : 20-methylcholanthrene (MCA); 1 : 2,5 : 6-dibenzanthracene (DBA); and 3 : 4-

---

[*] Holder of a NATO fellowship granted by the Italian National Research Council.

benzpyrene (BP), a structurally related non-carcinogenic control (anthracene) and tri*cyclo*quinazoline, a heterocyclic nitrogen carcinogen (kindly provided by Dr. R. W. Baldwin)) were used. Solutions were prepared by adding carcinogens in the form of fine particles to inactivated calf serum (100 µg/ml.) and incubation at 37° for 6 h with continuous gentle stirring. The serum was centrifuged at 13,000g for 0·5 h at 4° and passed through a 'Millipore' filter. Appropriate dilutions of serum were added to the culture media to give a final concentration of carcinogen (confirmed by fluorimetry or radioactivity measurements) of 5–22 µg/ml.

Localization of carcinogens in cells. Cell cultures were incubated for 2–24 h in media containing carcinogen or anthracene, mounted in fresh medium, and examined by fluorescence microscopy with activation from 360 mµ to 400 mµ. The same cells were examined by phase-contrast microscopy and after staining for acid phosphatase by the Gomori technique[10], with or without prior fixation in 1–4 per cent glutaraldehyde in isotonic phosphate buffer, pH 7·0, at 4°, for 2 h.

All the cell types examined after exposure to carcinogens were found to contain brilliant fluorescing granules in the cytoplasm (Figs. 1–3). The granules concerned appeared dense by phase-contrast microscopy and their distribution in individual cells and in the different cell types corresponded with that of lysosomes. Careful examination and photography of the same groups of cells by fluorescence microscopy and light microscopy after acid phosphatase staining showed that identical organelles contained the fluorescing carcinogens and lead sulphide deposit. No fluorescence was seen in background cytoplasm, mitochondria or nuclei. All the carcinogens examined, and anthracene, showed a similar intracellular distribution. With the hydrocarbons fluorescence was light blue or blue-violet; with tri*cyclo*quinazoline it was yellow.

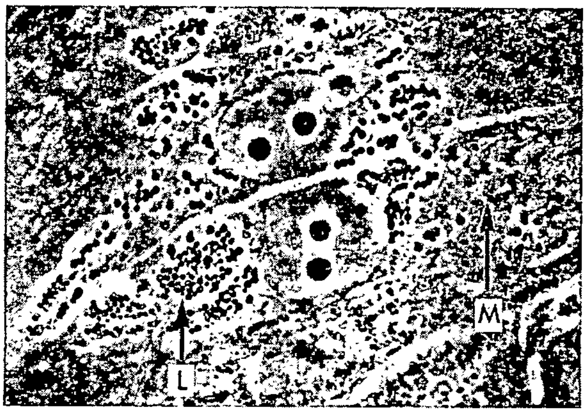

Fig. 1. Monkey kidney cells in culture, unfixed and examined by phase-contrast microscopy. The dense lysosomes (*L*), which are mainly in a perinuclear position, are readily distinguished from the less dense, filamentous mitochondria (*M*), most of which lie in the peripheral cytoplasm (× *c*. 870)

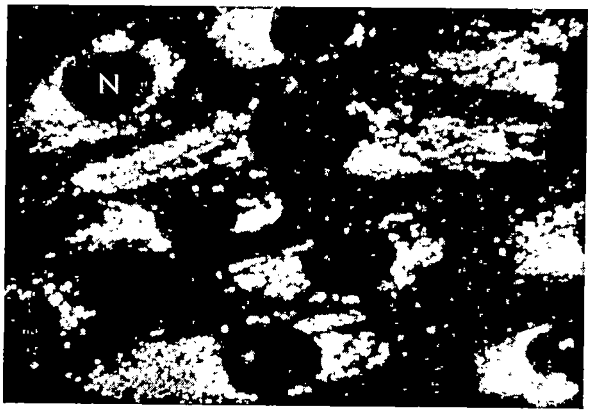

Fig. 2. Monkey kidney cells in culture, 24 h after exposure to 20-methylcholanthrene, examined without fixation by fluorescence microscopy. Lysosomes containing carcinogen fluoresce light blue, while nuclei (*N*) and peripheral cytoplasm containing mitochrondria show no fluorescence (× *c*. 390)

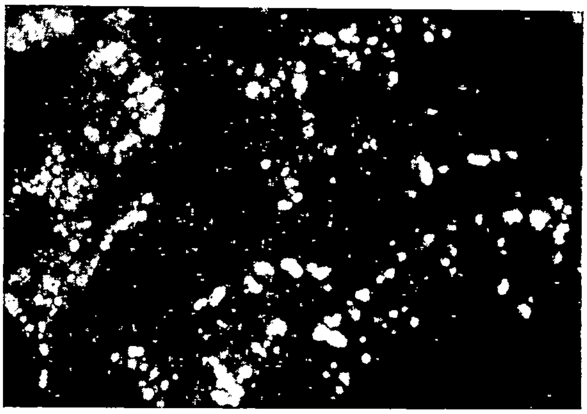

Fig. 3. Mouse macrophages in culture, 24 h after exposure to, 9,10-dimethyl-1 : 2-benzanthracene, unfixed but counterstained with euchrysine, showing light blue fluorescence of lysosomes in the cytoplasm (× *c*. 870)

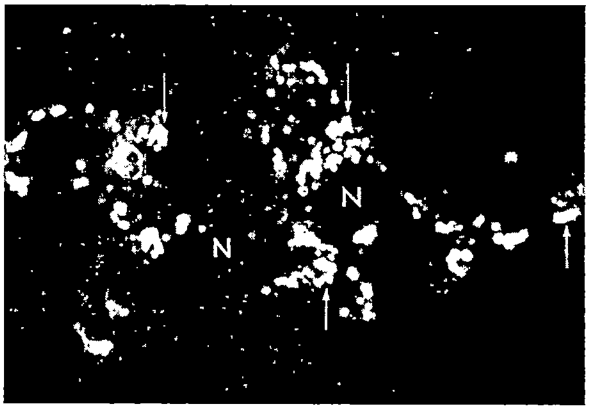

Fig. 4. HeLa cells in culture exposed 24 h previously to 3 : 4-benzpyrene, unfixed and showing fluorescence of lysosomes, many of which, as indicated by the arrows, tend to be concentrated as caps over one pole of the unstained nuclei (*N*) (× *c*. 390)

We conclude that the hydrocarbon carcinogens are taken up by cells and selectively concentrated in lysosomes. A possible objection to this interpretation is that the carcinogen is also present elsewhere in the cells but with its fluorescence quenched. Although quenching of fluorescence of aromatic hydrocarbons is less likely to occur than that of compounds with more reactive chemical groups, it was thought necessary to check this possibility. Cells were incubated for 24 h with medium containing 5 µg/ml. of 1 : 2,5 : 6-dibenzanthracene uniformly labelled with tritium (Radiochemical Centre, Amersham). After incubation for a further 2 h in medium without carcinogen, the cells were fixed with 1 per cent acetic acid (v/v) and coated with Kodak '*AR* 10' emulsion for autoradiography. Exposures of 8 days gave abundant granules, the distribution of which corresponded exactly with that of the lysosomes, none being present in any part of the nuclei except immediately adjacent to the lysosomes and none in areas of cytoplasm rich in mitochondria but without lysosomes. It is concluded that if any carcinogen is present in parts of the cells other than the lysosomes the amount is too small to detect by the methods used in our investigations.

In order to obtain information on the duration of fluorescence, monkey kidney cells were incubated with all four carcinogens and anthracene for 24 h and then incubated in fresh medium without carcinogens for varying periods before examination by fluorescence microscopy. Incubation for 24 h in fresh medium greatly reduced the intensity of anthracene fluorescence, which was sometimes yellowish rather than blue. After 48 h the anthracene fluorescence had virtually disappeared, but the carcinogen fluorescence was little changed, apart from the presence in some cells in addition to the typical lysosomal fluorescence of a weaker more diffuse area of fluorescence in a paranuclear zone. The only other change noted was that the fluorescence of cells just exposed to BP was violet or blue-violet, whereas that of cells exposed 24 h previously was blue. These preliminary observations suggest that the non-carcinogenic anthracene may be more rapidly metabolized or lost from lysosomes than the carcinogens, and further investigations on more closely related carcinogenic and non-carcinogenic compounds are in progress.

In vivo *experiments*. The objection could also be raised that the behaviour of cells cultured *in vitro* might not be representative of what happens *in vivo*. Experiments were therefore carried out on mice. DMBA was dissolved in paraffin (m.p. 45°) and 0·2 ml. containing 100 μg carcinogen introduced subcutaneously in adult male *VSBS/NIMR* mice. After 1 week the animals were killed, the paraffin removed and impressions and spreads of connective tissue cells examined. Although the cytological detail was less well shown than in cultured cells, in all but a few apparently dead cells the fluorescence of the carcinogen was confined to cytoplasmic granules having the distribution of lysosomes.

As others had previously observed[2,4,5] polybenzenoid hydrocarbon carcinogens are taken up into the cytoplasm of cells. We have demonstrated, further, that the hydrocarbons we have used are specifically concentrated in lysosomes, and not in mitochondria as Graffi[2] supposed. De Duve[11] and his colleagues have shown that lysosomes contain hydrolytic and other enzymes, including acid phosphatase, acid DNase, acid RNase and acid protease (cathepsin). The properties of lysosomes have been conveniently summarized at a recent Ciba Foundation symposium[12]. Evidence is accumulating that lysosomes of living cells take up neutral red[12], and we have shown that they also selectively concentrate a number of basic dyes and drugs, including several aminoacridines, chloroquine, quinine, stilbamidine, antrycide and ethidium. Since the hydrocarbon carcinogens are uncharged, it is clear that basicity is not a necessary requirement for a compound to be taken up into lysosomes. From repeated observation it seems that the carcinogens are concentrated in preformed intracellular organelles (primary lysosomes) rather than phagocytic vacuoles (phagosomes), although the possibility cannot be excluded that carcinogens enter the cells in micropinocytotic vacuoles which eventually fuse with the primary lysosomes. On the other hand, if any crystals of carcinogen are present (as in some of our preliminary experiments not involving serum solubilization) these are incorporated into typical phagosomes.

The concentration of carcinogens in lysosomes has a number of interesting implications. First, it is likely that for some time no metabolic conversion takes place. The observations of Sloane and his colleagues[5] on fluorescence spectroscopy *in vivo* in rabbit ear chambers, and after uptake of hydrocarbon carcinogens by cells *in vitro*, suggest an initial solution of the carcinogens similar to that produced in serum. With BP, emission at short wave-lengths decreased and that at long wave-lengths increased quite rapidly. This parallels the observations of Doniach *et al.*[3] and ourselves that the initial fluorescence with BP is blue-violet whereas after 24 h it is blue. With the other carcinogens no change in fluorescence is detectable. Our observations indicate that fluorescence of anthracene disappears much more rapidly, presumably owing to loss from lysosomes or metabolic conversion, than that of the carcinogens. Whether conversion by hydroxylation and coupling with glucuronic acid occurs in the lysosomes themselves cannot be decided on available evidence. The characteristic proteins to which carcinogens become bound[7] may well be lysosomal. However, it seems unlikely that protein binding is a necessary event in carcinogenesis since the stable compound tri*cyclo*quinazoline, which is a potent carcinogen, is not bound to protein[13], although we have found it to be concentrated in lysosomes like the polybenzenoid hydrocarbons.

Secondly, in at least some cells the carcinogens appear to decrease the stability of lysosomal membranes, as shown by acid phosphatase staining of the lysosomes of unfixed macrophages when they have taken up carcinogens. This occurs to a much smaller extent in kidney cells, and Mr. J. Dingle kindly allows us to quote his observation that hydrocarbon carcinogens have much less dramatic effects on the integrity of isolated kidney lysosomes than comparable concentrations of vitamin A. Nevertheless, high concentrations of carcinogens in lysosomes could well bring about considerable release into the cytoplasm of lysosomal enzymes, and this provides an explanation for the well-known cytotoxicity of hydrocarbon carcinogens both *in vivo* and *in vitro*. Attention was directed to this phenomenon long ago by Haddow[14] and others, and the evidence has recently been reviewed by Vasiliev and Guelstein[15].

Lower concentrations of carcinogens could bring about gradual release into the cytoplasm over long periods of enzyme such as DNase, RNase and protease, which might well damage the mechanisms controlling cell division—whatever these may be—without impairing the capacity of the cells to divide. Since the carcinogens have marked electron-donating and accepting properties[16], charge transfer with constituents of the lysosomal membranes could be involved in the enzyme activation.

Deckers-Passau *et al.*[17] had previously demonstrated activation of lysosomal enzymes in livers of rats treated with dimethylaminoazobenzene; these changes were more marked in animals with riboflavin deficiency, which enhances the carcinogenic effect of the dye. More recently, Nodes and Reid[18] observed within one week of feeding rats 3′-methyl-4-dimethylaminoazobenzene a marked rise in the acid RNase activity in the supernatant fraction, indicating activation of the lysosomal enzyme. Carbon tetrachloride is also known both to activate lysosomal enzymes of liver[19] and to be carcinogenic in some species[20].

The hypothesis that lysosomes are involved in carcinogenesis might provide a simple explanation for co-carcinogenesis, that is, the enhancement of the effects of small doses of carcinogens by subsequent treatment with unrelated chemicals. Three of the most effective co-carcinogenic agents for hydrocarbon carcinogens are croton oil[21], non-ionic detergents of the 'Tween' group[22] and hyperoxia[23]. All these affect lysosomes. We have observed that treatment of cultured macrophages and monkey kidney cells with croton oil (10 μg per ml. in serum added to medium), 'Tween 60' (0·001 per cent w/v, in culture medium) or 95 per cent oxygen + 5 per cent carbon dioxide for 12 h allows lysosomal enzymes to be stained in unfixed preparations, indicating that the permeability of the lysosomal membranes has been increased. Effects of detergents and the role of lysosomes in oxygen toxicity have been investigated in some detail and the results will be presented elsewhere. All the co-carcinogens could enhance effects of small amounts of carcinogen in the lysosomal membrane. Since virus infections often cause activation of lysosomal enzymes[24], interaction with carcinogens is also possible at the level of the lysosomes. Likewise, the decreased interferon production in cells after treatment with hydrocarbon carcinogens[25] may be attributable to release of lysosomal enzymes which inhibit interferon synthesis or bring about its intracellular destruction.

The toxicity of DMBA to adrenal and testicular cells of treated rats[26,27] may also be due to lysosomal damage. From the experiments of Richter and Saini[4] it is clear that spermatogonia and spermatocytes accumulate large amounts of hydrocarbon carcinogens in cytoplasmic organelles, which from their distribution appear to be lysosomes. The selective toxicity of DMBA for these cells, not shown by other hydrocarbon carcinogens, is presumably due to the particular configuration of the former, perhaps its non-planar structure[28].

One of the factors making polybenzenoid hydrocarbons so efficient as carcinogens could be that they act as selecting as well as inducing agents. The importance of selection at the cellular level has already been discussed[29]. The results summarized by Vasiliev and Guelstein[15] show that in many instances growth of normal cells is inhibited by concentrations of hydrocarbons that are well tolerated by malignant cells. It follows that in tissues where relatively high concentrations of carcinogens are present malignant cells will be at a competitive advantage. Selective inhibition of normal cells could favour emergence of malignant cell clones in several ways. One is purely mechanical: in skin and other epithelia multiplication of cells in the basal layer produces a steady movement of cells towards the surface: potentially malignant cells could be eliminated by this rising tide, but selective inhibition of normal cell division would give the malignant cells a greater chance of securing a 'foothold' from which to multiply out. A second possible selective mechanism which has recently attracted attention is the partial suppression by carcinogens of the immune cellular response which is concerned in the elimination of tumour cells differing antigenically from host cells[30].

Our results provide no evidence for direct interaction of hydrocarbon carcinogens with genetic material. Earlier experiments of others indicating interaction of carcinogens with DNA have recently been criticized by Giovanella *et al.*[8], who conclude that the likelihood of such an interaction producing a cancer-specific mutation is extremely remote. Many powerful carcinogens are weakly, if at all, mutagenic, and many efficient mutagens are non-carcinogenic in standard test situations. Giovanella and his colleagues reiterate the earlier conclusion of the Wisconsin group that carcinogenic hydrocarbons initiate the cancerous transformation through specific binding to key proteins. However, as already stated here, examples such as tri*cyclo*quinazoline suggest that protein binding is not a necessary property of a carcinogen. Pitot and Heidelberger[31] explain the apparently genetic perpetuation of carcinogen-induced metabolic changes on the basis of specific disruptions in metabolic regulatory circuits. We would offer an alternative hypothesis not dependent on analogies with control mechanisms in micro-organisms: that the primary target of carcinogens in cells is the lysosomes, and that secondary effects (probably due to released lysosomal enzymes, and perhaps involving DNA or RNA) are perpetuated when the cells continue to divide. Chromosome breaks and other changes sometimes observed in carcinogen-induced tumour cells, and in virus-infected cells, could also be produced by lysosomal enzymes. Whatever hypothesis is adopted, the fact that carcinogens are selectively concentrated in lysosomes and remain there for relatively long periods has to be taken into account.

We thank Mr. M. R. Young for help with the microscopy and photomicrography.

EXTRACTION AND PURIFICATION OF CALCITONIN

By Dr. A. BAGHDIANTZ, Dr. G. V. FOSTER, A. EDWARDS, Dr. M. A. KUMAR, Miss E. SLACK,
Dr. H. A. SOLIMAN and Dr. I. MacINTYRE

Department of Chemical Pathology, Postgraduate Medical School, London, W.12

COPP *et al.*[1] postulated the existence of a plasma-calcium lowering hormone on the basis of perfusion experiments in dogs. We confirmed the existence of this new hormone, calcitonin[2]. Copp *et al.*[1] had concluded that the parathyroid glands were the source. However, our recent investigations have shown that calcitonin is a thyroid hormone secreted in response to a high plasma calcium[3].

Presumably due to their calcitonin content, thyroid extracts from dog, rat, ox, pig, monkey and goat lower plasma calcium when injected into rats[3-5]. Hirsch *et al.*[6] first reported 50- to 100-fold purification of these extracts by centrifugation at 100,000*g* followed by gel-filtration on 'Sephadex *G*-50'.

Methods of extraction and purification of calcitonin and some investigations of its nature and properties are described here.

A method of calcitonin bio-assay was developed in which the material to be tested is infused for 1 hr into the tail-vein of a 150-g rat of the Hammersmith piebald strain (Kumar, Foster and MacIntyre, unpublished results). The rats were killed immediately after the infusion and the plasma calcium measured by flame spectrophotometry[7]. Until a standard preparation was produced, one unit of activity was defined as one-tenth of the amount of calcitonin necessary to produce a fall of 0·5 m.equiv. calcium/l.

Pig thyroid was found to be a richer source than ox. It also had the theoretical advantage that the pig thyroid does not contain parathyroid glands[8]. Fresh pig glands were defatted by repeated washing with acetone and the dry powder taken as the starting material.

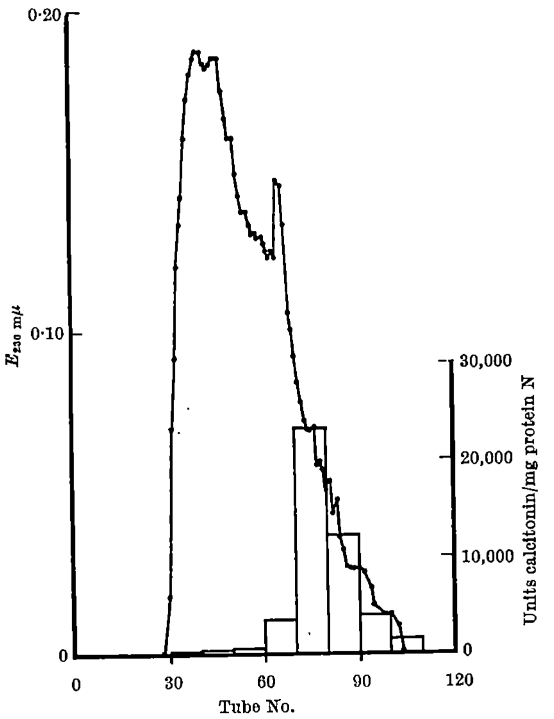

Fig. 1. Gel-filtration of calcitonin on 'Sephadex *G*-100'. 0·1 M acetate, *p*H 4·6, containing 0·2 M sodium chloride was used as eluant and 5-ml. fractions were collected. Activities reported are the average of assays done in triplicate as described in the text. In three consecutive runs values of 23,000, 11,000 and 15,000 units/mg protein nitrogen were obtained in the most active fractions. Minor peaks and variations occurred in the inactive region of the curve with different batches

Crude extract. 100 g of acetone-dried thyroid tissue was stirred with 1 l. of 0·2 N hydrochloric acid at 60°–70° for 5 min. The mixture was allowed to stand at room temperature for 1 h and then filtered through muslin, and the residue was washed with 1 l. of water and the washings added to the filtrate. This will be referred to as crude extract. The potency at this stage was about 180 units/mg protein nitrogen estimated by the Lowry method[9]. When dialysed at 4° for up to 48 h against 0·1 M acetate buffer at *p*H 4·6 or 0·1 N hydrochloric acid in 24/32 'Visking' tubing all the activity remained with the dialysis residue. Extract dialysed against 0·2 N hydrochloric acid was dried from the frozen state and taken up in 0·1 M buffers of *p*H 2–9. No activity was lost below *p*H 4·6 after 2 weeks at 4°. Above *p*H 7·2 a precipitate formed in the crude extract at 4° and some activity was lost with the precipitate. Other samples of dried dialysed crude extract were taken up in 0·1 M acetate buffer at *p*H 4·6. 1·0 M sodium chloride precipitated most of the inactive protein. When the supernatant from such a precipitate was increased to 2·0 M with sodium chloride a further precipitate formed which contained most of the activity.

Salt fractionation. These observations were used for purification as follows. 1 l. of crude extract was dialysed at 4° overnight in 24/32 'Visking' tubing against 0·1 M acetate buffer at 4°. 1 l. of 2 M sodium chloride was added gradually with stirring and the solution left for 12 h at 4°. The resulting precipitate was separated by centrifugation and discarded and an equal volume of 3 M sodium chloride was added to the supernate and allowed to stand for 12 h at 4°. The active precipitate was isolated by centrifugation and dissolved in 0·1 N hydrochloric acid or 0·1 M acetate buffer. The resulting solution had a potency of about 1,200 units/mg protein nitrogen. It was relatively stable to boiling and lost 12 per cent activity in 15 min, 46 per cent in 30 min and 77 per cent in 2 h in 0·1 M acetate buffer at *p*H 4·6. Incubation of the extract with pepsin or trypsin at a *p*H of 3 and 7, respectively, resulted in complete loss of activity after 6 h. Appropriate controls were carried out. Boiling with 1·0 N hydrochloric acid or 1·0 N sodium hydroxide for 1 h resulted in complete loss of activity.

Gel-filtration. The salt-precipitated extract was further purified by gel-filtration. 20 ml. of extract in 0·1 M acetate buffer *p*H 4·6, containing also 0·2 M sodium chloride, was applied to a column of 'Sephadex *G*-100' (82 cm × 2·5 cm) equilibrated with the same solution. 5-ml. fractions were collected at a flow rate of 30 ml./h and the extinction at 230 mμ measured in each tube. Groups of 10 tubes were pooled for assay. Fig. 1 shows a typical result. The main activity was eluted in tubes 70–90.

The most active fraction had a potency of 23,000 units/mg protein nitrogen: infusion of only 0·4 μg protein nitrogen lowered rat plasma calcium by 10 per cent. At this stage of purification the activity passed through the 'Visking' membranes (24/32) which retained the activity of crude extracts. This suggests that calcitonin was associated with larger molecules in the crude extract.

Discussion

The thyroid calcium-lowering hormone, calcitonin, is a polypeptide or low molecular weight protein. Its solubility at acid *p*H and loss of activity on incubation with trypsin and pepsin excludes thyroxin as the active principle. Further, Hirsch *et al.*[4] found no reduction in calcium in the rat when thyroxin was injected. The calcium-lowering activity penetrated the gel matrix of 'Sephadex *G*-100'. Calcitonin is therefore distinct from thyroglobulin, which has a molecular weight of 600,000 (ref. 10), far above the exclusion limit of 100,000.

The potency of calcitonin and its wide distribution in mammalian thyroids suggests that it is of major importance in calcium homœostasis. This may entail considerable revision of present concepts.

This work was done during the tenure of an advanced research fellowship of the American Heart Association (G. V. F.). Support was likewise received from the Central Treaty Organization (A. B.), the United Arab Republic (H. A. S.) and the Medical Research Council (I. MacI.). We thank Paines and Byrne, Ltd., for supplying us with acetone-dried thyroid.

CALCITONIN PRODUCTION AND THE MITOCHONDRION-RICH CELLS OF THE DOG THYROID

By Dr. G. V. FOSTER*, Dr. I. MacINTYRE and Dr. A. G. E. PEARSE

Departments of Chemical Pathology and Histochemistry,
Postgraduate Medical School, London, W.12

THE possibility of a thyroid origin for calcitonin was suggested by Hirsch *et al.*[1], who extracted a hypocalcæmic substance from the thyroid glands of a number of mammalian species. More recent investigations by Foster *et al.*[2] in the goat have established the thyroid origin of calcitonin in that animal, and we are reporting here the results of histochemical investigations carried out on dog thyroid glands perfused with high and low calcium blood. Earlier investigations (unpublished) in parallel with the perfusion experiments of Kumar *et al.*[3], using histochemical techniques and electron microscopy, failed to show any change in the cells of parathyroids subjected to high (7 m.equiv./l.) or low (4 m.equiv./l.) calcium-levels for short periods (3 h).

In the dog thyroid, as in the human gland, two types of cell can be found in the acini. These are the preponderant principal cells and the so-called mitochondrion-rich cells[4]. The latter are present not only in the acini, but also in groups or nodes which lie between adjacent acini, a position which has been described as 'parafollicular' (Fig. 1). Cells in this position are usually regarded as tangentially cut normal acinar cells. Histochemical methods show that they have an entirely different enzyme pattern and must be regarded as metabolically distinct even though they are clearly acinar in origin (that is, not truly interfollicular).

Investigations carried out on the human thyroid by Tremblay and Pearse[5] showed that the mitochondrion-rich cells possessed an oxidative enzyme activity many times higher for most systems than the adjacent principal cells. In the latter the distribution of mitochondria was predominantly on the luminal side of the nucleus while in the mitochondrion-rich cells it was uniform throughout. This observation is true also for the parafollicular cells in the dog thyroid. As can be seen from Fig. 2, they contain a much higher level of mitochondrial α-glycerophosphate dehydrogenase than the acinar (principal) cells. Levels of this enzyme are comparable to those found in the principal cells of the parathyroid and in the β-cells of the pancreatic islets (Fig. 3).

Control thyroid-parathyroid glands (calcium-level, 5·5 m.equiv./l.) were obtained from 4 animals at the beginning of the perfusion experiments. The remaining thyroid-parathyroid glands were then perfused with high (7 m.equiv./l.) or low (4 m.equiv./l.) calcium blood for 3 h by the technique of Kumar *et al.*[3].

Thin slices of all the glands were quenched, immediately after removal, in liquid air (− 185°) and stored at −90° until ready for cutting. Cryostat sections (4–8μ) of all glands were simultaneously incubated for demonstration of the following enzymes: acid phosphatase, alkaline phosphatase, α-glycerophosphate dehydrogenase (menadione), NADH-diaphorase and non-specific (α-naphthyl and indoxyl) esterases. Techniques used were those given by Pearse[6]. Selected blocks were freeze-dried in a thermoelectrically controlled apparatus[7] and subjected to formalin

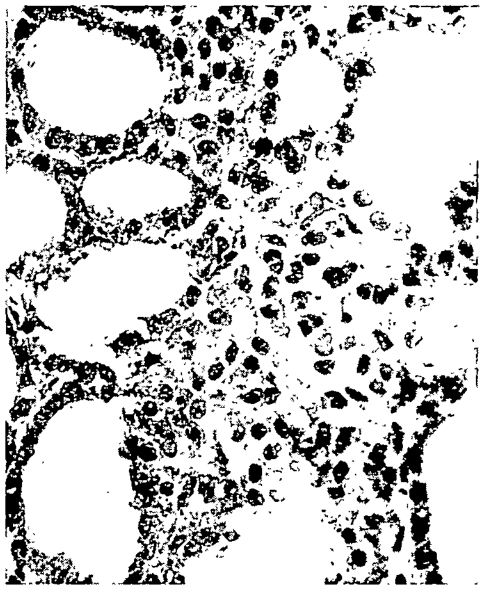

Fig. 1. 4μ Cryostat section. Shows distribution of parafollicular cells in normal dog thyroid (hæmatoxylin and eosin, × 370)

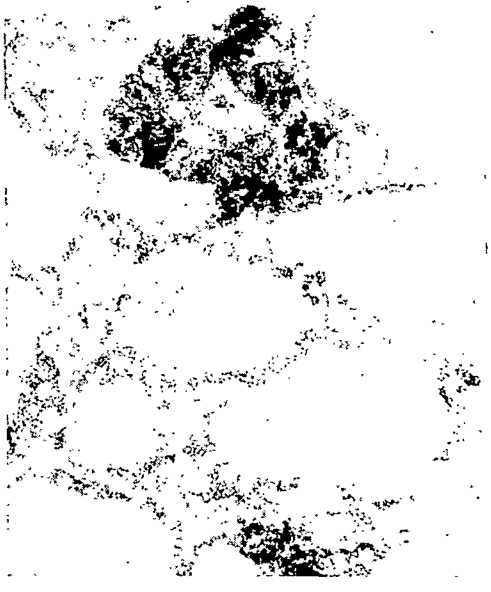

Fig. 2. 8μ Cryostat section. Shows high mitochondrial α-glycerophosphate dehydrogenase in the mitochondrion-rich cells. Normal dog thyroid (× 370)

vapour treatment for 1 h at 80° (ref. 8). These blocks were used to examine the distribution and activity of adrenergic nerves and of fluorescent material within the cells. The position of the parafollicular cells relative to the basement membrane was established and confirmed in periodic acid–Schiff-stained sections.

---

*Advanced Research Fellow of the American Heart Association.

In the glands perfused with high calcium blood a definite increase in acid phosphatase was noted in the mitochondrion-rich cells (Fig. 4), and to a lesser extent in the principal cells also. The normal level of acid phosphatase in the thyroid gland is moderate, though much higher than in the parathyroid gland. There was no difference between control glands and those perfused with low calcium blood.

No difference could be detected with NADH-diaphorase, but α-glycerophosphate levels were lower in the mitochondrion-rich cells of the high calcium glands.

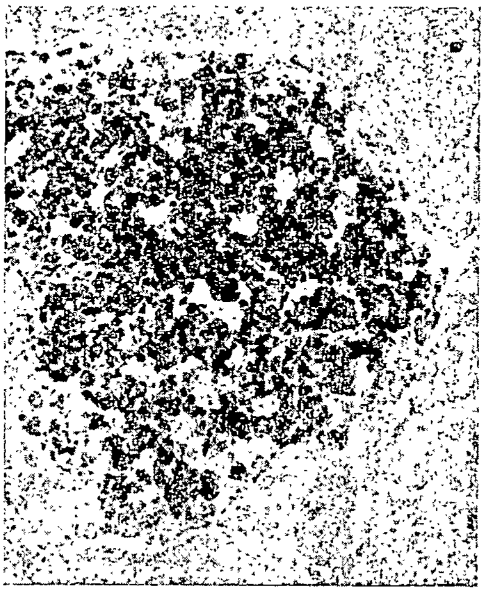

Fig. 3. 4μ Cryostat section. Rat pancreas. Very high α-glycerophosphate dehydrogenase levels in the β cells of an islet of Langerhans (× 150)

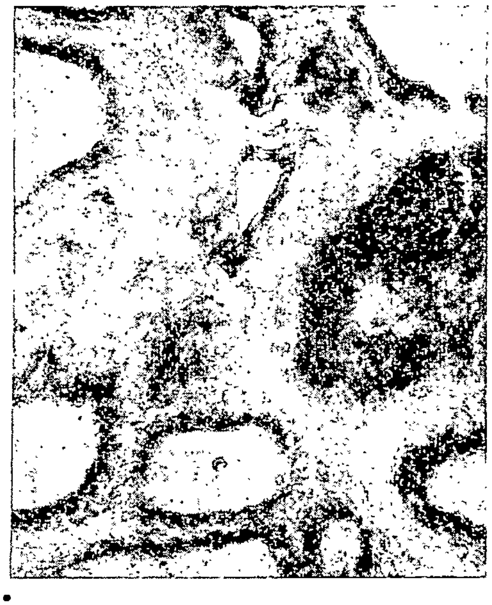

Fig. 4. 8μ Cryostat section. Acid phosphatase in parafollicular cells. High calcium perfused gland (× 370)

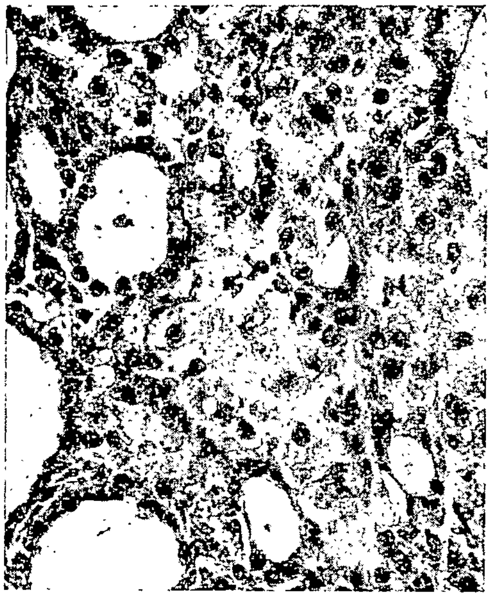

Fig. 5. 4μ Cryostat section. Extensive vacuolation in intra- and para-follicular cells. Low calcium perfused gland (hæmatoxylin and eosin, × 370)

The levels of non-specific (indoxyl) esterase were distinctly lower after high calcium perfusion than in controls from the same animals. No corresponding elevation could be seen in the low calcium-treated glands.

Cryostat sections of the low-calcium glands stained with hæmatoxylin and eosin revealed an unusual sensitivity of the intra- and para-follicular mitochondrion-rich cells to low calcium-levels. Extensive vacuolation was present in the cells (Fig. 5). Although this may well be regarded as an artefact there is no reason to ignore its significance on that account (it was not present in sections incubated for various enzymes, in which the cells were presumably protected by the more or less isotonic media used).

Discussion

The results reported here indicate very strongly that it is the mitochondrion-rich cells which are responsible for the secretion of calcitonin. It is interesting to note that Seecof[4] regarded the two thyroid cell types described in his paper as comparable to the α and β cells of the pituitary or pancreatic islets. Tremblay and Pearse[5] suggested that the mitochondrion-rich cells, and the closely related Askanazay or Hürthle cells, "might conceivably be carrying out some function other than the production of thyroglobulin and thyroxin".

Further work is necessary to confirm our results. Morphological and cytochemical investigations at the electron microscope level are in progress to this end. As soon as calcitonin samples of sufficient purity are obtained attempts will be made to produce antibodies to the hormone. If successful, immunofluorescent investigations will then be carried out.

We thank Mr. J. Bancroft for his assistance and Mr. W. Brackenbury for the photomicrographs.

L FORM INDUCTION OF NATURALLY OCCURRING METHICILLIN-RESISTANT STRAINS OF *Staphylococcus aureus*

By Dr. BENJAMIN M. KAGAN, Dr. ELMO R. MARTIN and Prof. GORDON T. STEWART

Departments of Pediatrics, Cedars of Lebanon Hospital, Division of Cedars-Sinai Medical Center,
and the School of Medicine, University of California, Los Angeles, California,
and Queen Mary's Hospital for Children, Carshalton, Surrey

RECURRENCE of clinical staphylococcal infections occurs in some patients who have been treated with penicillin or methicillin until they are clinically well and cultures are negative for staphylococci. Although the 'persister' state is well known, it is not well understood. This phenomenon, as described by Kagan *et al.*[1], may be due to the capacity of staphylococci to convert to and revert from *L* forms. Staphylococcal *L* forms can be maintained on media containing up to 5,000 μg/ml. of methicillin or penicillin. This high degree of resistance carries serious implications if similar *L* forms occur *in vivo*.

The induction of staphylococcal *L* forms in the presence of methicillin was reported by Kagan *et al.*[1]. The methods used were similar to those adopted by Dienes and Sharp[2], Marston[3], and Prozorovskii[4]. These investigators induced staphylococcal *L* forms from penicillin *G*-sensitive strains in a medium containing penicillin *G* and a high concentration of sodium chloride.

Work reported by Kagan *et al.*[1] described *L* form induction in methicillin-resistant staphylococci. However, these methicillin-resistant strains of staphylococci were laboratory induced.

The appearance of 71 isolates of *Staphylococcus aureus*, which were resistant to all available therapeutic penicillins including methicillin, was reported by Stewart and Holt[5]. These strains were resistant to 20 μg/ml. methicillin or more. The methicillin-resistant organism first appeared, passively, in a nasal carrier; it spread into 8 out of 48 wards in Queen Mary's Hospital for Children at Carshalton, Surrey, England. It spread eventually to fifty patients, most of whom developed no active infection. However, there were two deaths. One of these was a child who died from septicæmia after acquiring the organism in a surgical wound. This patient acquired the organism while receiving methicillin and streptomycin. Despite a change in therapy to erythromycin after positive blood cultures were obtained, the child died. At necropsy the same resistant strain was recovered from the spleen, right ventricle and lung; as in previous instances it was of phage type 75/77.

The appearance of naturally occurring methicillin-resistant staphylococci led to the work reported here of *L* form induction of naturally occurring methicillin-resistant staphylococci.

Five strains (1–5) of naturally occurring methicillin-resistant staphylococci from Carshalton, England, were investigated.

The medium used was brain heart infusion agar ('Difco') with 5 per cent sodium chloride and 20 per cent heat inactivated filtered human serum. Some plates contained this same medium and up to 500 μg/ml. methicillin. Other plates were used with the same medium without antibiotic but with a central well in which was placed 500 or 1,000 μg methicillin in 0·05 ml. distilled water.

The *Staphylococcus aureus* cultures were seeded to 2·5 per cent rabbit blood brain heart infusion agar ('Difco') for isolation of pure cultures. Single hæmolytic colonies were transferred to brain heart infusion broth and incubated approximately 18 h. Cultures were then transferred by cotton swab to the methicillin *L* form inducing media. Cultures were then incubated at 37° C and kept from dehydrating by the use of rubber bands to seal the Petri dishes.

Table 1 shows the results of culturing the five strains of *Staphylococcus aureus* on medium containing 500 μg/ml. methicillin. There were no granular colonies and *L* forms predominated in the medium containing 500 μg/ml. methicillin.

Table 1. *L* Form Induction of Naturally Occurring Methicillin-resistant *Staphylococcus aureus* Strains

	Staphylococcus aureus strain numbers 1	2	3	4	5
Numbers of *L* form colonies	20	75	98	128	76
Numbers of normal colonies	0	3	0	15	0

The central well method with 500–1,000 μg/ml. methicillin also yielded staphylococcal *L* forms. In general, as the concentration of methicillin increased in the serum-containing medium, the confluent bacterial growth was replaced by discrete bacterial colonies mixed with a few

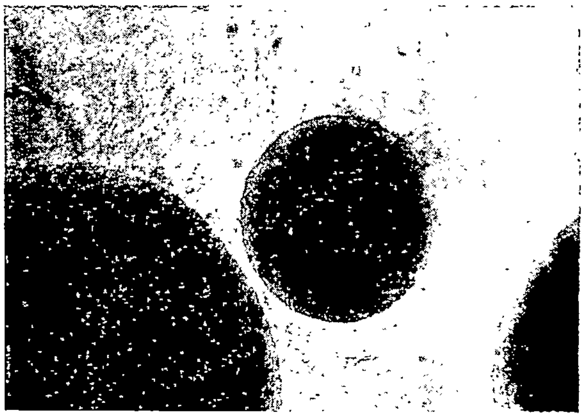

Fig. 1. Appearance of normal staphylococcal colonies (× c. 66)

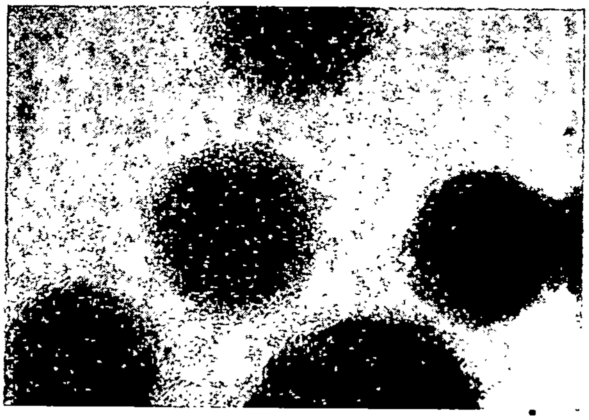

Fig. 2. A group of granular colonies × c. 66)

L colonies and some small as well as large granular colonies, and, finally, only *L* forms (Figs. 1–7).

L colony formation was readily obtained from all five strains of methicillin-resistant *Staphylococcus aureus* by methicillin induction. Some reversion to parent methicillin-resistant staphylococcal forms occurred on subsequent transfer of *L* forms to media containing 500 µg/ml. forms obtained from parent *Staphylococcus aureus* strains that were sensitive to methicillin.

Granular colonies appearing in close proximity to the *L* forms of staphylococci (Figs. 4 and 5) when transferred to media containing up to 500 µg/ml. of methicillin reproduced identical granular type colonies. These granular colonies were medium large and opaque to white in colour; their cells were Gram-positive and swollen. On the same medium, but lacking methicillin, seedings from the granular colony reverted to normal pigmented *Staphylococcus aureus* colonies. Cells from the latter colonies were normal in appearance. The granular, as well as *L*, forms were both maintained successfully in repeated transfers on medium containing 500 µg/ml. methicillin. Unlike the parent forms, when granular colonies were cultured continuously in medium containing methicillin, *L* phase variants did not appear.

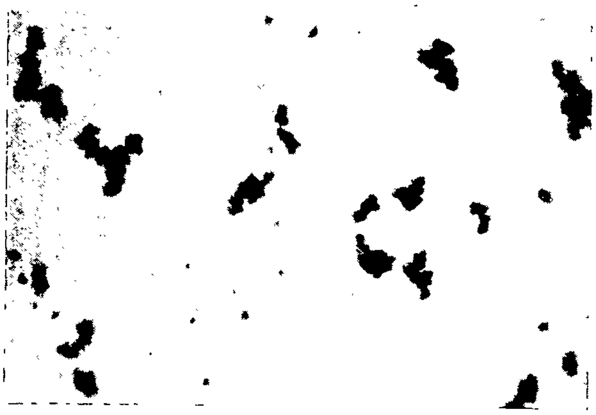

Fig. 3. A Gram stain of swollen cocci from the granular colonies (× *c*. 660)

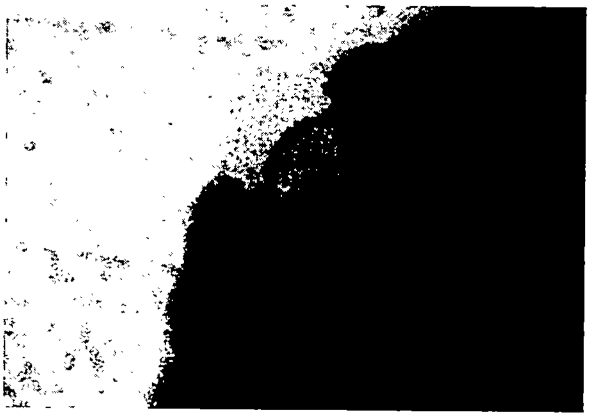

Fig. 4. *L* colony being overgrown by a large granular type colony (× *c*. 66)

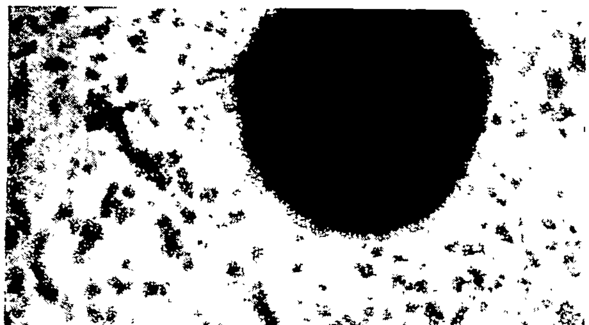

Fig. 5. *L* colony and a granular colony growing in close proximity to each other (× *c*. 66)

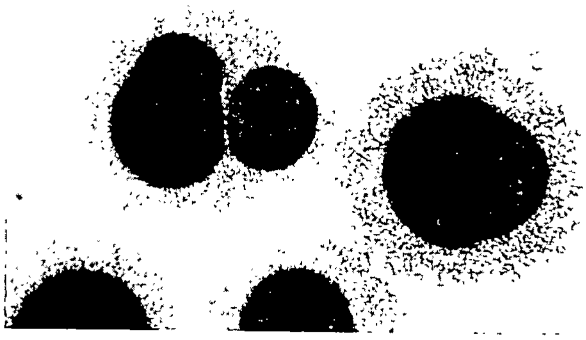

Fig. 6. A pure culture *L* form of *S. aureus* strain No. 3 after 60 h incubation (× *c*. 66)

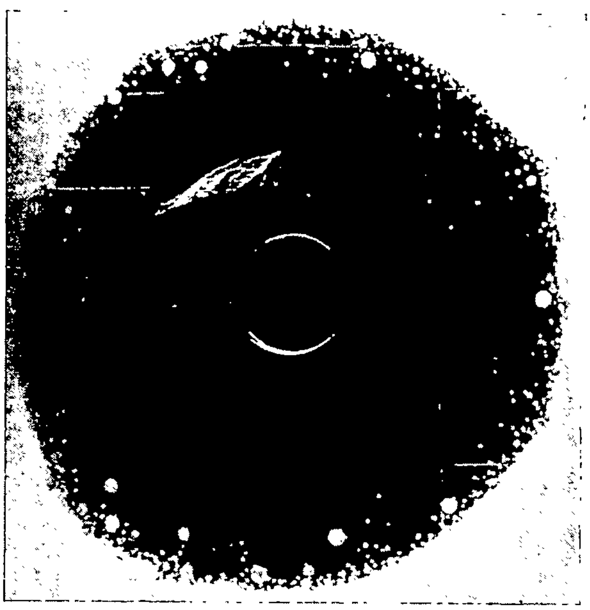

Fig. 7. Centre well method with 500 µg methicillin added to well. Small pin point *L* forms and larger granular colonies are visible

The significance or relation between the granular and *L* forms is not clear, especially since the granular forms failed to produce *L* forms on subsequent cultures in the presence of increased concentration of methicillin. The reversion from granular to normal pigmented *Staphylococcus aureus* colonies in the absence of methicillin resembles the reversion of *G* forms or small colony penicillin variants of *Staphylococcus aureus* reported by Youmans *et al.*[6].

Some have considered the swollen or granular type cells to be intermediate between *L* forms and normal forms of staphylococci[2,3,7]. However, this granular type of growth could be a mutation entirely unrelated to the *L* form. From the fact that the granular forms of these particular strains could not be induced to *L* forms, it would appear that at least under these conditions they are not a stage in the development of *L* forms. Simultaneous occurrence of granular and *L* forms in close proximity may not be limited to conditions *in vitro* but also may appear *in vivo* in the 'persister' state. To understand more about the 'persister' state of staphylococcal infections, further investigations with both forms may prove important.

ML: A NEW ANTIGEN FOUND IN LEUKÆMIAS AND MAMMARY TUMOURS OF THE MOUSE

By Dr. BURGHARD STÜCK, Dr. EDWARD A. BOYSE, Dr. LLOYD J. OLD
and ELIZABETH A. CARSWELL

Division of Experimental Chemotherapy, Sloan-Kettering Institute for Cancer Research,
Sloan-Kettering Division, Cornell Medical College, New York, and Department
of Pathology, New York University School of Medicine, New York

CYTOTOXIC antibodies with specific activity against leukæmia cells can be prepared in mice by immunization with leukæmias of various types. Antisera of this sort have been used to define three distinct antigenic systems in mouse leukæmias: (1) The *G* antigen[1] of leukæmias induced by Gross virus[2]; (2) the *FMR* antigen[3] of leukæmias induced by Friend[4], Moloney[5] or Rauscher viruses[6]; (3) the *TL* (thymus leukæmia) antigen[7] of spontaneous leukæmias, leukæmias induced by a variety of agents, and normal thymus of certain strains.

A fourth antigenic system associated with mouse leukæmia is described here. The antigen has been detected in several leukæmias of the *DBA*/2 strain and in the mammary tissue and mammary tumours of mouse strains which are infected with the mammary tumour agent. In view of its tissue distribution, the appropriate designation for this antigen is *ML* (mammary leukæmia).

The antigen was first detected by iso-immunization of *C57BL*/6 mice with a *DBA*/2 spontaneous leukæmia, *DBA*/2 ♀ *SL*1. Antiserum from these mice was absorbed *in vivo* in normal *DBA*/2 mice in order to remove cytotoxic isoantibodies. This absorbed serum was cytotoxic for *DBA*/2 ♀ *SL*1, another spontaneous leukæmia, *DBA*/2 ♂ *SL*2, and a urethan-induced leukæmia, *DBA*/2 ♂ *U*12; there was no cytotoxic effect on several transplanted leukæmias induced in adult *DBA*/2 mice by percutaneous application of 7,12-dimethylbenzanthracene (DMBA) (Table 1).

Antisera with *ML* specificity have been prepared also by immunization of *C57BL*/6 mice with *DBA*/2 ♂ *SL*2,

Table 1. Cytotoxic Tests* on *DBA*/2 Leukæmias with the Serum *C57BL*/6 ♀ anti *DBA*/2 ♀ *SL*1 absorbed *in vivo*† in Normal *DBA*/2 Mice

Table 4. Leukæmias of Strains other than *DBA/2* that did not absorb Activity from *ML* Antisera

	A	*C57BL/6*	*BALB/c*	*AKR*	*C3H/An*	*C3Hf/Bi*	*C58*	I	$(C57BL/6 \times A)F_1$
Spontaneous	2	4	2	2			1	1	
Chemical carcinogen									
DMBA				2	2		3		
Urethan			1	2					
X-radiation	3	5	3						1
Virus									
Gross		1	1			1			
Moloney		2							
Rauscher		2							

and by immunization of strains other than *C57BL/6* [*BALB/c*, *I*, $(C3H/An \times I)F_1$ and $(C57BL/6 \times A)F_1$] with either *DBA/2* ♀ *SL*1 or *DBA/2* ♂ *SL*2. Six antisera prepared by prolonged immunization of strains *C57BL/6*, *I* or $(C3H/An \times I)F_1$ with five individual DMBA-induced *DBA/2* leukæmias, and absorbed *in vivo* in *DBA/2*, contained no *ML* antibody. Eight antisera prepared in *DBA/2* against eight histo-incompatible leukæmias of various types showed no cytotoxic activity against *DBA/2* ♀ *SL*1 or *DBA/2* ♂ *SL*2.

The distribution of *ML* antigen was investigated by the more sensitive technique of absorption of specific activity from *ML* antisera. The three leukæmias which were sensitive in the direct cytotoxic test removed *ML* activity (Table 2). Absorption was also observed with three leukæmias that showed little or no sensitivity in the direct cytotoxic test—*DBA/2* ♀ DMBA 12, and the two long-transplanted *DBA/2* ascites leukæmias *P* 1534 (spontaneous) and *L* 1210 (induced by 20-methylcholanthrene). The other DMBA-induced leukæmias, including two (Nos. 17 and 18) which were induced by neonatal injection of DMBA, were uniformly *ML*−. Table 3 shows that absorption of *ML* antiserum with a variety of tissues of normal *DBA/2* mice was entirely negative. No leukæmia of any strain other than *DBA/2* has absorbed activity from *ML* antiserum (Table 4). The absorption data clearly distinguish *ML* from the *G*, *FMR* and the *TL* systems. Both *DBA/2* ♀ *SL*1 and *DBA/2* ♂ *SL*2 carry the *TL* antigen as well as *ML* specificity (both absorb *TL* activity from the serum *C57BL/6 anti ASL*1 (ref. 7)). Absorption of *ML* antisera with the prototype *TL*+ leukæmias *ERLD* and *ASL*1 (ref. 7) does not reduce *ML* activity.

A variety of chemically induced sarcomas of strains *A*, *C3H*, *BALB/c* and $(C3H/An \times I)F_1$, including both ascites and solid forms, did not absorb *ML* antibody. In contrast, *ML* activity was removed by spontaneous mammary tumours from mice of strains carrying the mammary tumour agent. Twenty-seven primary mammary tumours were examined, of which 11 are shown in Table 5. Twenty tumours, including 8 of those listed in Table 5, gave clear-cut absorption. The remaining 7 tumours showed incomplete absorption under the conditions of the test. The mammary tumours were obtained from strains *C3H/An* (5 tumours), *DBA/2* (8 tumours), *A* (2 tumours) and $(C3H/An \times I)F_1$ (12 tumours). The specificity of absorption of *ML* activity by mammary tumours was confirmed by tests with *H*-2 and *TL* antisera; non-specific absorption of these antibodies by mammary tumour cells did not occur. Mammary tissue obtained from lactating mice 5–10 days *post partum* has also been used in absorption tests. *ML* antibody was absorbed by mammary tissue from strains *DBA/2* and *C3H/An*, which have the mammary tumour agent, but not by mammary tissue from the agent-free *C57BL/6* and *BALB/c* strains. No tissue from strains *C3H/An* and $(C3H/An \times I)F_1$ other than mammary gland and mammary tumour removed *ML* activity.

The *ML* antisera used in this work contained an unidentified antibody with cytotoxic activity for *DBA/2* thymus. This antibody was not absorbed by *ML*+ mammary tumour tissue.

Table 5. Cytotoxic Tests with the Serum *C57BL/6* ♂ anti *DBA/2* ♂ *SL*2 absorbed *in vivo* in Normal *DBA/2* Mice

Absorption of *ML* antibody by primary spontaneous mammary tumours*

* Mammary tumour cells were obtained by mincing the solid tumour with scissors and washing the suspended cells three times. These preparations contained 50–80 per cent cells stained by trypan blue.

The finding of an antigen that is shared by leukæmias and tissues from normal mice of certain strains suggests a parallel with the *TL* system[7]. In the case of *ML*, however, there are clear indications that the antigen is associated with presence of a known virus, the mammary tumour agent. If indeed *ML* is determined by the mammary tumour agent, this may indicate either that this virus can be leukæmogenic in some circumstances or that the presence of *ML* antigen in *DBA/2* leukæmias is an example of antigenic conversion[8] brought about by the infection of leukæmia cells with an unrelated virus.

USE OF SIMPLE GEL-DIFFUSION TECHNIQUES TO ASSIGN ANTIGENIC MARKERS TO NATIVE PROTEINS

By PROF. IRVING FINGER
Biology Department, Haverford College, Haverford, Pennsylvania

MACROMOLECULES have been characterized with precision in terms of amino-acid sequences in proteins, sugar sequences of polysaccharides and, less successfully, nucleotide sequences of nucleic acids. These achievements still have not left the biologist with practical means of examining many aspects of biological control of macromolecule synthesis and function. So far, detailed analyses of the fate of individual sequences of the macromolecules understandably have been neglected in investigations of such problems as complementation and isozyme formation. Instead, reliance has been placed on indicators of overall structural changes, such as changes in net charge, enzymatic efficiences, etc.[1]. This article suggests an approach to identification of distinct sites on macromolecules which combines simplicity of apparatus with rapidity and ease of analysis. By gel-diffusion methods macromolecules can be characterized in their native, undegraded state provided that they are antigenic. Less than 1 mg of material is needed, and this need not be entirely pure. A requirement, however, is that a supply of a number of related antigens be available; a readily available source would be the products of mutants, although in theory any cross-reacting substances would suffice.

The surface antigens of *Paramecium* can serve as a prototype system and meet all these requisites. The class dealt with is that of the *C* serotypes and the five used were all naturally occurring variants at the same locus[2]. These antigens are large, of approximately 250,000 molecular weight, almost exclusively protein, with a minor carbohydrate constituent, and are soluble in saline[3]. The antigenic structure in terms of operationally defined determinants has been examined in detail. In addition, the specificities of antibodies possessed by individual sera have been assigned, and the determinants possessed by an antigen have been classified into those that are unique and those that are shared with other antigens. Finally, procedures for tagging individual 'determinants and their possible utility in the investigation of several biological problems are described.

A combination of two gel-diffusion methods is used: double diffusion in tubes[4], and double diffusion on microscope slides (modified from Ouchterlony)[5]. Preer tubes are used primarily to determine approximate equivalence ratios of antigen and sera: those concentrations yielding an intense, sharp band of precipitate, a band that does not change location in the agar column from its position when first visible. For most of the sera used, this was the amount of antigen extracted from 10^7 cells and suspended in 1 ml.

Once equivalence concentrations are assigned, the Ouchterlony technique is the sole gel-diffusion method used. Behind this method lies a simple principle: lines of antigen–antibody precipitate meet and fuse when there are no antibodies diffusing from the serum well that can distinguish the two antigens being compared. If the antigens share no determinants—with reference to the antibodies available—the bands will cross, with neither precipitate forming an apparent barrier to the diffusion of unrelated antigen or antibody molecules. However, if two antigens are related, although not identical, a spur may form near the point of fusion as an extension of the precipitate. This spur is made up of the antigen that reacts exclusively with at least one fraction of the population of antibody molecules[6].

Equivalence or near-equivalence concentrations of reactants are chosen for use in Ouchterlony patterns because the band formed is dense and narrow and because artefactual spurs tend to form when either reactant is in extreme antigen or antibody excess. Tests for genuineness of spurs observed are described here. In essence, spur formation in gels is analogous to a liquid precipitin test for the presence in the supernatant of antibody specific for homologous antigen, following maximal precipitation by a cross-reacting antigen. In gel-diffusion the presence of unprecipitated antibody after interaction of serum with one antigen solution is detected by the formation of a precipitate trapped in the agar. The free antibodies diffusing unimpeded through the original band are precipitated by the second antigen preparation. Thus, a spur is both indicative of multiple antibodies in a serum and of distinctive antigens. We may therefore say that, operationally, one determinant difference can enable two antigens to be discriminated.

Assigning Determinants to Each Antigen

When any two *C* antigens were compared side by side with serum prepared against one of the antigens, in most instances a spur formed with the immunizing (homologous) antigen. In the few instances when a serum did not give rise to a spur, it could be shown by other methods, for example, the ability to immobilize differentially living cells of the two strains from which the antigens were extracted, that the serum lacked the ability to discriminate between the antigens. The significant observation, from the point of view of antigenic identity, is that if any serum makes distinctions between two antigens, regardless of the rarity of such a serum, the two antigens must be considered different in some respect.

However, when two antigens are compared using as a source of antibodies a serum prepared against a third cross-reacting antigen, no particular pattern should be anticipated other than a band fronting each well; complete fusion, spurs or crosses are all apt to occur. Using several *C* antisera, all non-homologous antigens can be compared with each other. The complete listing of spurs observed can be viewed in a relatively simple framework formed by a single set of premises: (*a*) Any antigen that gives a spur with another antigen possesses a determinant that is missing in the second antigen. (*b*) This same determinant is shared by the antigen used in eliciting the antibodies, the immunizing antigen.

An illustration of spur and fusion patterns observed with one anti-*C* serum is shown in Fig. 1. This is a photograph of a microscope slide stained for protein in which the serum used was prepared against 197 *C* antigen.

The spurs observed with several antisera are presented in Table 1. Each number represents a separate *C* antigen; each isolated from a genetically distinct stock. In the first column are listed all the possible pairings. To facilitate analysis, a certain amount of redundancy is incorporated into the presentation of the results. Thus, each antigen is represented several times: once when paired with the homologous immunizing antigen, again when each non-homologous antigen is compared with it, and a third time when it is compared in turn with each non-homologous antigen. The antigen forming a definite spur as a continuation of the precipitate appearing in front of its well is recorded as 'direction of spur'. Blank

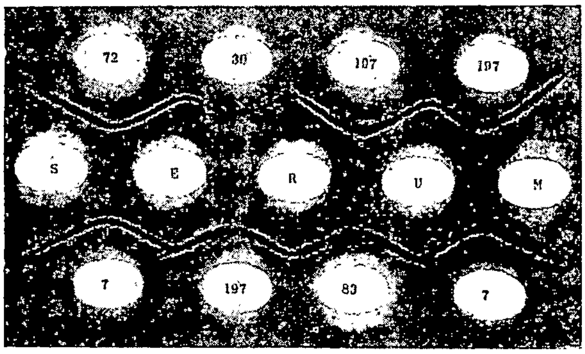

Fig. 1. Gel-diffusion reactions of purified homologous and heterologous immobilization antigens with an anti-197 serum. Antigen from stock 197 (the homologous strain) forms spurs with 7 and 30 antigens; 83 antigen forms a spur with 7 antigen. All other antigen combinations fuse in 'reactions of identity'

spaces represent complete crosses, or poorly defined spurs.

Three categories are of significance. These classes of reactions and the interpretations ascribed to them are:

(1) An antigen forms a spur with every other antigen, with the exception of the immunizing antigen. This antigen shares with the antigen originally used to elicit the antibodies a determinant missing in all the other antigens.

(2) One antigen, regardless of the antigen it is compared with, fails to form a spur. This antigen is missing at least one determinant that is possessed by all the other antigens.

(3) Two antigens form bands that fuse, but with every other antigen (except the immunizing antigen) each of these antigens forms a spur. These two antigens together with the immunizing antigen share a determinant lacking in all other antigens. There obviously are several variations on this particular set of relationships especially as the number of antigens being compared becomes larger than the five used here.

How these interpretations have been applied to the *C* serotypes can be seen by comparing the reactions actually observed (Table 1) with a matrix of determinants (Table 2) derived from these patterns. Each letter in the matrix represents a determinant; a determinant is defined simply as an antigenic entity recognized by an operation in gel diffusion, that is, inability or ability to form a spur. This operational term undoubtedly has an intramolecular counterpart, but whether it is an amino-acid substitution, a folding pattern, etc., of course cannot be stated from the gel-diffusion information alone.

Examples of each of these three principles will serve to illustrate the actual mechanics for evolving the matrix. A letter, *G*, was placed in the 30 and 7 rows because, with anti-7 serum, 30 and 7 gave a spur when tested with each of the other antigens: 197, 72 and 83. Thus, following the first principle, it can be said that 30 shares with the antigen used to elicit the antibodies, 7, a determinant missing in every other antigen. This determinant is represented by the letter *G*.

Table 1. DIRECTION OF SPURS FORMED BY CROSS-REACTING ANTIGENS IN OUCHTERLONY GEL-DIFFUSION PATTERNS

Test sera Anti-7		Anti-83		Anti-197	
Antigen* neighbours	Direction of spur	Antigen neighbours	Direction of spur	Antigen neighbours	Direction of spur
7–30	7	83–30		197–30	197

Table 2. MATRIX OF ANTIGENIC DETERMINANTS FOR *C* SEROTYPES AS DETERMINED BY GEL DIFFUSION

Serotype	Determinants										
30*C*		*F*	*G*	*H*	*I*	*J*		*L*	*M*		*O*
7*C*	*C*	*F*	*G*		*I*	*J*			*M*		
72*C*		*F*		*H*		*J*	*K*	*L*	*M*		
83*C*				*H*	*I*				*M*	*N*	*O*
197*C*		*F*		*H*	*I*		*K*	*L*		*N*	*O*

The determinant *F* in the matrix is present in every antigen save 83. Assignment of this determinant was based on the observation that, with anti-7 serum, 83 failed to form a spur when paired with either 30, 197 or 72. According to the second principle, these three antigens share a determinant, together with the immunizing antigen, that is missing in 83. This is not the only possible explanation, but the simplest, and one not contradicted by any other reaction.

An example of the third principle would be the reactions of 197 and 30 antigens when tested with anti-83 serum. Both these antigens form a spur with 7 and 72, but fuse with each other. Therefore, we can conclude that 197, 30 and 83 (the immunizing antigen) share a common determinant denoted here by the letter *O*. Incidentally, this particular 83 antiserum apparently did not contain antibodies against the *M* and *N* determinants. Otherwise, 83, in comparisons with 30 and 197, would have formed a spur. The 7 and 197 antisera, on the other hand, were able to distinguish their respective homologous antigens from all the cross-reacting antigens.

The completed matrix represents the fewest number of determinants that are required to account for the antigenic specificities observed. When as many determinants as possible have been assigned, the final step is to check whether: (*a*) each antigen has at least one determinant that is missing from a second antigen; (*b*) each antigen shares at least one determinant with a second antigen.

The first requirement stems from the observation that the immunizing antigen generally forms a spur with every other antigen (Table 1). If the determinants assigned thus far fail to fulfil this requirement, then a unique determinant is added to the matrix. For example, *C* had to be tacked on to the determinants for 7 because 7 had no other determinant to distinguish it from 30. On the other hand, 30 can be distinguished from, say, 72 by the determinants *G*, *I* and *O*, from 7 by the *H*, *L* and *O* determinants, etc.

On the basis of analysis with only a few sera, initially each antigen was arbitrarily assigned a unique determinant to account for the spur observed with the immunizing antigen. It was only as more sera became available, and additional determinants were recognized, that it was seen that for most antigens the homologous serum reaction was also consistent with a unique distribution of the shared determinants such as described previously for 30. This finding also suggested the possibility that as more sera were prepared, the number of determinants might correspondingly increase *ad infinitum*. However, with more than twice the number of sera utilized in setting up the matrix in Table 1 as was available in the original investigations (18 compared with 8)[7], only three determinants have had to be added, suggesting that a limit was being approached.

The second requirement for shared determinants stems from the fact that all the antigens form a precipitate with serum prepared against any one of them. This requirement is easily met with the *C* serotypes. However, were this not the case, an additional common determinant would have to be added to all antigens, for example, *X*. Should a serum be found that is unable to distinguish any of the antigens, every antigen pairing giving rise to a reaction of identity (fusion), then the existence of a common determinant could be assumed.

Assigning Antibodies to Individual Antisera

Given an antigen with its set of distinguishing determinants, certain rather limited predictions can be made concerning the kinds of antibodies that should be elicited by injection of this antigen. Because some of the *C* antigens have as many as eight determinants, it would appear that some anti-*C* sera might have as many as eight kinds of antibodies. However, it is well known that rabbits vary considerably in their ability to respond to an antigen, and some antigens are more effective immunizing agents than others. The fact that so many pairings—even between antigens with many determinants—gave single spurs or complete fusion indicates that most, if not all, sera have relatively few detectable kinds of antibodies. With the information from the matrix, it now became possible to describe in detail the antibody content of any particular serum in qualitative terms.

For example, in a 197 antiserum, one may expect to find at the most antibodies against *F*, *H*, *I*, *K*, *L*, *N* and *O* determinants. Knowing the determinant constitution of every antigen, each kind of antibody can be identified by noting whether a particular pattern of spurs is observed, assuming the presence of each antibody singly. The predicted reactions in Table 3 for antibody against each determinant were derived from a comparison of the sets of determinants comprising each antigen (Table 2). For example, 72 possesses *H* which 7 lacks. A spur with 72 is therefore to be expected when it is paired with 7, if *H* antibodies are present. To determine whether *H* antibodies are present, the column headed *H* is scanned. The expectation of fusion, of course, can be ignored in most cases because few sera have just one kind of antibody. The crucial prediction is the kinds of spur anticipated, which are expected to occur among four pairings. Reading across the row from each pairing, it can be seen that with one pairing, 7–83, other antibodies that might be present in the serum (such as anti-*F*) could give rise to spurs also, but these would be in opposite directions and the double spurs would appear as a cross. Thus, this particular pairing might give ambiguous results. Again, if this serum had both *I* and *K* antibodies, then when 30 and 72 are compared a double spur might form. However, were only *I* antibodies present, a single spur alongside the 30 well would appear. In this manner, by checking the reactions observed with those predicted for each column, the presence of antibodies specific for each determinant can often be determined for every *C* antiserum. In those instances where unique determinants are assigned an antigen (such as *C* in 7), it can be assumed that antibody specific for this determinant will probably be found in the homologous serum.

Obtaining Determinant-specific Reactions

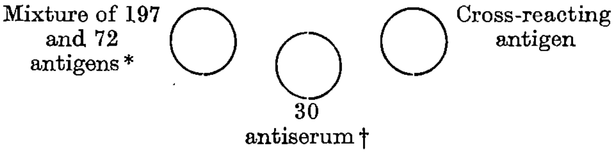
When the procedures already outlined here were followed, it proved possible to demonstrate that several antisera had but two or three kinds of antibodies defined in terms of specificity towards operationally distinguishable determinants. Consequently, a particular determinant generally could be assigned to a new antigen on the basis of whether it reacted to form characteristic patterns of spurs when compared with each antigen. For example, if a serum were shown to contain anti-*F* and anti-*K* antibodies exclusively, an antigen could be tested for the presence of *F* and *K* by comparing each antigen with it and checking for the reactions predicted by the matrix, as was done in making up Table 3.

Table 3. Reactions of Antibodies against Specific Determinants in 197 Antiserum

Antigen neighbours	Expected antibody specificities *F*	*H*	*I*	*K*	*L*	*N*	*O*
30–197	*f*	*f*	*f*	197	*f*	*f*	*f*
30–7	*f*	30	*f*	—	30	—	30
30–72	*f*	*f*	30	72	*f*	—	30
30–83	30	*f*	*f*	—	30	83	*f*
7–197	*f*	197	*f*	197	197	197	197
7–72	*f*	72	7	72	72	—	—
77–83	7	83	*f*	—	—	83	83
72–197	*f*	*f*	197	*f*	*f*	197	197
72–83	72	*f*	83	72	72	83	83
197–83	197	*f*	*f*	197	197	*f*	*f*

f, fusion. –, no band. Numbers in body of Table indicate direction of spur.

The usual method for securing specific antibody is to absorb selectively all antibodies but those having the desired specificity. Any absorption can also be carried out directly in gel by choosing appropriate patterns. Indeed, as has been noted here, spur formation itself is a consequence of selective absorption. Thus, if one wanted to determine whether a cross-reacting antigen possessed determinant *G*, the following pattern could be set up to obtain a reaction with antibody specific to *G*:



* Possesses *F*, *H*, *I*, *J*, *K*, *L*, *M*, *N* and *O* determinants.
† Containing several kinds of antibodies, including *G* specific ones.

Those antibodies with *G* specificity would be free to diffuse through the 197–72 precipitate and form a spur with the cross-reacting antigen. If *G* were absent in the cross-reacting antigen, complete fusion of the two bands would be evident were all other determinants possessed by the 30 antigen (the immunizing antigen) also shared by the cross-reacting antigen.

In sum, the presence of individual determinants on an antigen can be recognized either by assaying sera for antibody content and selecting the most specific or by selectively absorbing in gel.

Spurs as a Criterion for Partial Identity

It is critical for the success of the proposed analysis that spurs observed truly represent the reactions of a single antigenic species of molecules with specific antibodies. It is as a consequence of this interaction that a band of precipitate forms, the major portion of the length of which is a complex of antigen and cross-reacting antibody, and a smaller segment of which is a complex with specific antibody. In our experience the most common source of misinterpretation has been the presence in the system of a second unrelated antigen as an impurity in one antigen preparation. By a coincidence of concentrations, the band formed by this antigen may precisely overlie the original precipitate.

Fortunately, there are several tests for distinguishing pseudo from true spurs. In one, the serum is absorbed with the antigen solution not giving rise to the spur, and then the supernatant is allowed to diffuse against the suspect antigen solution. Antibody to impurity would have been left untouched by the absorbent, so that the position of the band formed with the test antigen would be the same as initially observed, allowing for dilution by absorbent. However, were the spur genuine, the band would shift in its position away from the antigen well since at least some cross-reacting antibody would have been removed. This test is best carried out in Preer double diffusion tubes where displacements in band positions can more accurately be measured.

In the second test, mixtures of the two antigen solutions in varying proportions are allowed to diffuse in separate Preer tubes against unabsorbed serum. If two bands are formed only when the suspect antigen solution is not in excess, then the spur is genuine. The appearance of two bands when either antigen solution is in excess speaks for an impurity. These predictions are based on the observations on a system comprised solely of homologous and cross-reacting antigen[4]. With the latter in excess, antibody capable of precipitating only homologous antigen is free to diffuse through the leading heterologous antigen–

antibody precipitate and form a second band as the antibody is precipitated by the trailing front of homologous antigen. With homologous antigen in excess, only one band was seen as all antibodies were precipitated by the leading front. An impurity might be expected to form a second band (or possibly even a third) independent of which antigen solution was in excess, since neither major antigen–antibody precipitate would act as a barrier to the passage of antibody directed against impurity.

A third check on the genuineness of a spur is the simplest. The antigen solution in question is placed in the central well of an Ouchterlony slide surrounded by a circle of wells, each well filled with a different cross-reacting serum. With a true spur situation a single continuous band should be found bordering the central well. The presence of an unrelated antigen would be revealed by the formation of a second band or a continuation of the precipitate in the regions of those sera with antibody directed against the impurity. Fig. 2 illustrates this for two preparations of *C* antigens. In *A* no impurities were present, and a spur formed by this antigen when compared with a heterologous antigen was apparently *bona fide*. Another antigen preparation that had an overlapping contaminant presented the pattern shown by *B*.

Procedures similar to those outlined here can also be used for discriminating between spurs due to cross-reactivity and those due to overlapping of two related antigens, such as might occur with a mixture of native and partially denatured antigens.

Limitations of Method

From the way in which data are accumulated, certain limitations inhere in this approach. For example, if all antisera available possess antibody in high titre directed against many determinants, then individual, discrete spurs may be replaced by crosses resulting from double spurs. This would effectively eliminate the possibility of arranging an unambiguous matrix. Also, if the antigens are not soluble, difficulties in free diffusion might arise, although particulate antigens have been successfully investigated in agar[8].

Should the concentrations of antigens be less than 10 γ/ml. or the sera be low in antibody content, precipitates, and especially spurs, might not be easily visible. With such systems, the approach to structural analysis of antigens suggested here can still be applied, substituting Preer tubes for Ouchterlony slides. In lieu of spur formation, the criterion for partial and complete identity becomes the number of bands formed subsequent to mixtures of antigens in varying proportions.

Other requirements for utilization of the procedures include at least partial purification of the antigen so that multiple bands are not a frequent occurrence, and the presence of precipitating as contrasted with univalent antibodies. However, these are requirements shared by most immunological methods and so cannot be considered uniquely restrictive.

Discussion

A relatively simple method has been outlined for providing antigenic macromolecules with multiple identifying characters. Such landmarks can be recognized individually without destroying the integrity of the antigen. The conclusion that a single species of molecules may possess many antigenic determinants is not unexpected in the light of several investigations on partially degraded antigens[9]. Intact antigens, however, hitherto have not readily lent themselves to such analysis, although there have been some exceptions[10]. A suggestion, perhaps unique, derived from this investigation is that an antigen which can elicit antibodies capable of distinguishing it from all cross-reacting antigens need not possess a unique determinant.

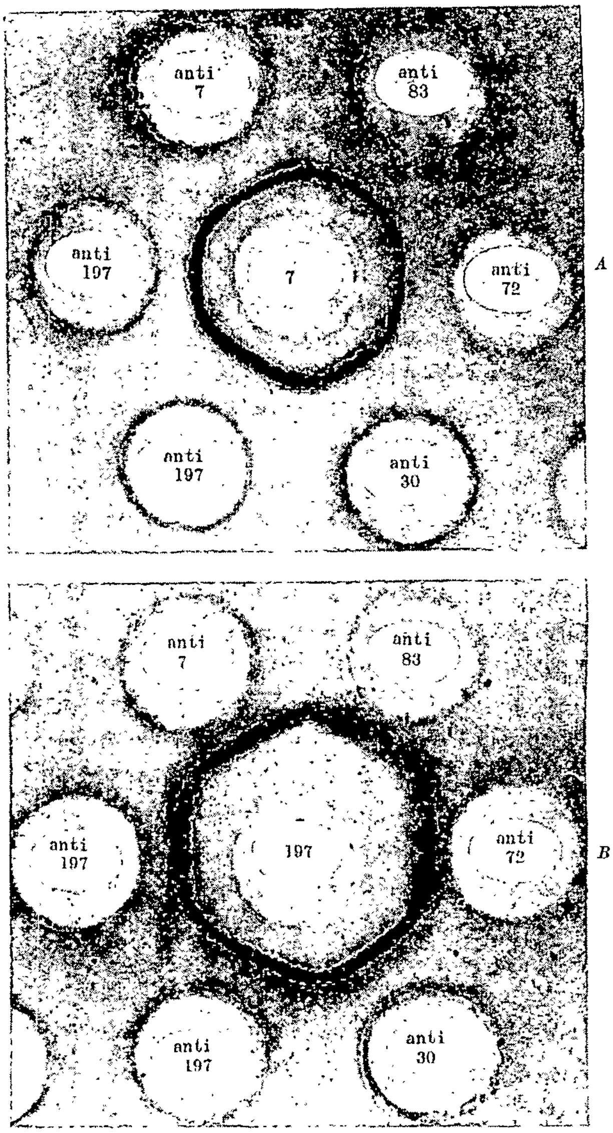


Fig. 2. A, Purified *C* antigen from stock 7 surrounded by six different anti-C sera in wells punched in agar on a microscope slide. The slide was dried, washed in saline and stained with aniline blue. *B*, Partially purified 197*C* antigen solution containing at least one other antigen. The two antigen–antibody precipitates with one of the anti-197 sera tend to overlap and could give the illusion of a spur when compared with a single antigen

Although naturally occurring mutants have provided the antigens used here, for certain purposes partially denatured or disrupted molecules that retain antigenicity may also serve as a collection of cross-reacting substances for determinant analysis. However, restraints might then be placed on interpretations of the role these determinants can assume in the native molecule where they may be hidden. Conceivably, relatively few sera may be needed for an analysis of antigens. The typical heterogeneity in the kinds of antibodies induced by immunization of different rabbits with the same antigen may provide in itself a source of antibodies capable of distinguishing antigens. Thus, a chronic barrier to the examination of many immunological phenomena is here turned to advantage.

Once a mosaic of determinants is assigned to a group of proteins, the fate of sub-units can be followed during the course of chemical manipulations or in their native state in living systems. For example, the method should prove helpful in complementation investigations where it would be highly desirable to compare the reconstituted products of mixtures of different mutants with wild-type protein, without being forced to rely on a single criterion. Wild-type and non-mutant protein could be compared to see whether all determinants of both parents are possessed by the new protein. Also, were the molecules capable of dissociation into sub-units retaining their antigenicity, specific sub-units might be recognized by their determinant characteristics. The time of appearance, localization and concentration changes of sub-units could then be followed. A description of the course of assembly of native proteins during development might also prove practicable at a finer level than previously attempted. A related area of considerable interest which would probably benefit from detailed analysis of sub-unit reassortment and aggregation is that of the control of the synthesis of isozymes[11].

In conjunction with other methods, it may also be possible for this technique to be useful in resolving certain problems of protein structure not otherwise easily attacked. For example, *Neurospora* adenylsuccinate synthetase mutants located at certain points within a cistron tend to restore enzymatic activity to a degree greater or less than would be expected based on their position within the linkage group[12]. Were a refolding of a polypeptide chain or a juxtaposition of sub-units responsible for a return to a near-native configuration[13], then conceivably the determinant construction of heterokaryons might be more like the wild-type than either parent separately or in combination—that is, a 'new' antigenic specificity might be found. The lack of agreement between the linearity of linkage and complementation maps possibly could be resolved were concomitant changes in determinant composition also known. Since antigenic specificity itself is known to be highly dependent on folding, conclusions about tertiary structure might also be drawn from determinant analysis.

The probability of success in extending this approach to systems other than the *Paramecium* immobilization antigens appears to be high. The *Paramecium* antigens that have been successfully used here are not particularly effective as immunizing agents, rarely eliciting sera with antibody concentrations as high as 200γ per ml. Particularly suitable would be an examination of evolutionary relationships among species and genera through a comparison of individual serum proteins, such as albumins. This, of course, would provide but a single criterion of ancestry and might in itself be misleading. Thus, one determinant difference between two albumins, and two differences between either of these and a third albumin, need not mean that the original albumins are more 'closely' related than is either to the third. The single determinant difference may be a consequence of several amino-acid substitutions, and each of the other determinant differences result from a single amino-acid difference.

The major advantage offered by this immunological approach is that a single parameter is not relied on to compare proteins. For example, a change in net charge that is a reflexion of a single amino-acid substitution may also be mimicked by the sum of several amino-acid changes. However, using the suggested antigenic analysis, the number of parameters is greatly increased as each determinant may be followed separately, and a single net effect is less likely to obscure several independent alterations.

RETENTION OF IMMUNOLOGICAL INFORMATION

By STAFF OF THE CHESTER BEATTY RESEARCH INSTITUTE,
ROYAL CANCER HOSPITAL, LONDON, S.W.3

(I) By Syngeneic Radiation Chimæras

By Dr. A. J. S. DAVIES, BARBARA DOE,
A. MARJORIE CROSS and E. V. ELLIOTT

It is recognized that immunological information developed in an adult mouse in response to antigenic challenge may be retained when the animal is irradiated and given syngeneic bone marrow but is not retained to the same extent after irradiation and injection of allogeneic bone marrow[1,2].

A further series of experiments concerned with the immune responses of syngeneic and allogeneic radiation chimæras to sheep red cells is here described. The results are examined in order to determine whether residual immunological activity after irradiation and bone marrow therapy must necessarily be attributed to persisting host cells.

Mice

Male mice of the Chester Beatty *CBA* and *BALB/c* and of the Harwell *CBA/T6T6* strains were used throughout. Host (*CBA*) mice were 10–15 weeks of age at the time of irradiation. Donor mice (*BALB/c* or *CBA/T6T6*) were 8–10 weeks of age when killed. The *CBA/T6T6* mice have marker chromosomes[3].

Immunization

(*a*) *Active.* Mice were immunized by intraperitoneal injection of 0·2 ml. of a 20 per cent suspension of sheep red blood cells in Alsever's solution, 20 and 13 days before irradiation and 60 days after irradiation.

Immune mice were bled from the retro-orbital sinus. Serial doubling dilutions were made of the serum in saline in 'Perspex' hæmagglutination tiles. Aliquots of thrice-washed sheep red cells were added to the tiles, which were kept at 37° C for not less than 2 h. The total titration volume was 0·05 ml. Titres were expressed as logarithms to the base two of the reciprocal of the final dilution showing macroscopically visible agglutination.

(*b*) *Passive.* Eighty inbred male *BALB/c* mice were immunized with sheep red cells on each of three occasions separated by a fortnight. Seven days after the third injection blood was taken from the mice, pooled and after 1 h at 4° C, to facilitate retraction of the clot, the immune serum was taken off.

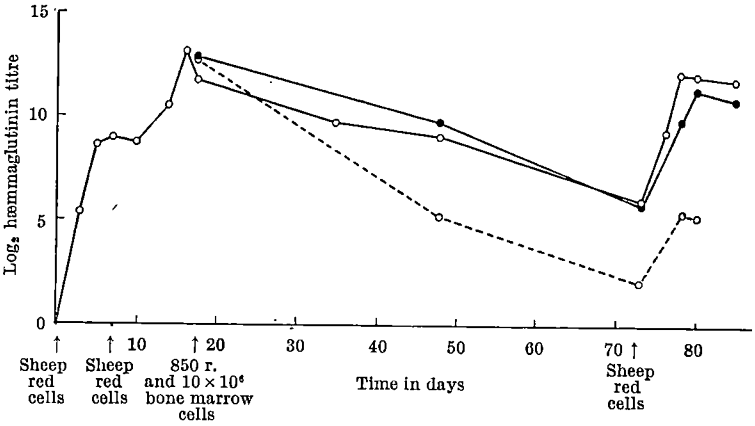

Fig. 1. The hæmagglutinin titres of various kinds of *BALB/c* mice in relation to time. (The normal mice were not irradiated)
—○—, Normal mice; —●—, *CBA/T6T6→CBA* syngeneic chimæras;
---○---, *BALB/c→CBA* allogeneic chimæras

0·4 ml. of this serum was injected intraperitoneally into each of 48 male *BALB/c* mice. Titrations were carried out on individual sera from all passively immunized mice 36 h, 6·5, 13·5, 20·5 and 27·5 days after their injection with immune serum. In all instances about 0·05 ml. of blood was withdrawn from the retro-orbital sinus. This afforded the minimum amount of serum that could be used in our titration system and represented about one-fortieth of the total blood volume of the mice. In these circumstances as only five bleedings were made on any one mouse it was felt that any effect of bleeding *per se* on serum titre could be ignored. The passively immunized mice were split into three groups of of 16 (four boxes with four mice in each). Two of these groups were subjected to 850-r. X-irradiation three days after passive immunization. One group of irradiated mice was injected intravenously with 10×10^6 cells of syngeneic (*BALB/c* bone marrow, the other with the same number of allogeneic (*CBA*) bone marrow cells, within 4 h of irradiation. The third, unirradiated group of mice was not subjected to further treatment. The irradiated mice would have died had they not been injected with bone marrow.

Irradiation and Bone Marrow Therapy

All mice received 850-r. total body dose at LD_{99}, 30 days and within 5 h were given, intravenously, 10×10^6 cells of either *BALB/c* (allogeneic) or *CBA/T6T6* (syngeneic) bone marrow in 0·4 ml. medium 199. Mice were maintained for 5 days before irradiation and 15 afterwards on a 20 per cent protein diet containing aureomycin (in the form of 'Aurofac' kindly supplied by the Cyanamid Chemical Corp., Ltd.; estimated dose 1 mg/mouse/day).

Cytological Check on Chimærism

Three and five days after receiving their third injection of sheep red cells (that is, 63 and 65 days after irradiation and bone marrow injection) groups of chimæras were injected with 'Colcemid' (4 mg/kg body-wt.) 1½ h prior to removal of half the spleens under ether anæsthesia. The piece of spleen removed was divided into two, half being retained for histological examination and half being made into a cell suspension in hypotonic sodium citrate preparatory to cytological examination[4] (syngeneic chimæras only).

Serological Check on Chimærism

Sixty days after irradiation red cells were removed from putative allogeneic chimæras and tested for their identity with appropriate iso-antisera[5].

Tests for Chimærism

(1) *Allogeneic chimæras.* All 20 animals surviving until 60 days after irradiation were found to have exclusively *BALB/c* (donor) red cells.

(2) *Syngeneic chimæras.* 289 cells in nine mice engaged in a response to a third injection of antigen were examined and were found all to be of donor (*CBA/T6T6*) type. This result agrees with the larger series of experiments[6] showing that host cells are rarely found 30, 50 or 100 days after 850-r. irradiated *CBA* mice have been injected with *CBA/T6T6* bone marrow.

Histology

Portions of the spleen removed on the third or fourth day after injection of sheep red cells (63 or 64 days after irradiation) were fixed and prepared for histological analysis. It was not possible to distinguish on the grounds of mitotic frequency between animals undergoing a primary and a secondary response to sheep red cells.

Titrations

(*a*) *Active immunity.* The titration results are given in Table 1 and Fig. 1. It can be seen that the response of normal *CBA* mice to a single injection of sheep red cells is rapid, giving a peak titre within 5–7 days. The primary response of syngeneic chimæras 60 days after irradiation (not shown in Fig. 1) was very similar and the peak titre was not significantly different from that of normal mice. The primary response of the allogeneic chimæras 60 days after irradiation was, however, significantly less than either normal mice or syngeneic chimæras.

The response of normal mice to a second injection of sheep red cells was also found to be rapid, giving a peak titre about 7 days after injection which was about 3–4 logs above the peak following the first injection. The titration values of the mice which were to be irradiated showed that they were behaving as normal before irradiation and could be regarded as satisfactory experimental material. It is noteworthy that titres observed in the syngeneic chimæras 41 and 66 days following the last contact with sheep red cells almost exactly paralleled those found in normal mice over the same period. In contrast the titres in the allogeneic chimæras were significantly lower than those of normal mice and of syngeneic chimæras.

The response of normal mice to a third injection of sheep cells was more rapid than that of the syngeneic

Table 2. DECLINE IN PASSIVE IMMUNITY OF THREE CLASSES OF *BALB/c* MICE EXPRESSED AS MEAN FALLS IN TITRE AND CALCULATED HALF-LIVES BETWEEN THE TIMES INDICATED AFTER PASSIVE IMMUNIZATION

Mice	Mean drop in titre and calculated half-lives during period indicated (see Fig. 2)							
	Period 1		Period 2		Period 3		Period 4	
	Mean drop in titre	Half-life	Mean drop in titre	Half-life	Mean drop in titre	Half-life	Mean drop in titre	Half-life
Normal	2·38 ± 1·45	2·10	1·50 ± 1·06	4·67	1·47 ± 0·89	4·76	1·20 ± 0·72	5·83
Syngeneic chimæras	2·86 ± 0·63	1·75	1·64 ± 0·48	4·27	2·00 ± 0·71	3·50	1·00 ± 0·93	7·00
Allogeneic chimæras	3·25 ± 1·09	1·54	2·88 ± 0·77	2·43	1·63 ± 0·85	4·29	1·50 ± 0·50	4·67

chimæras, but the peak titres were not significantly higher. In both cases the peaks reached about the level attained during a response of normal mice to a second injection of red cells. At twelve days the response of the syngeneic chimæras to a third injection was significantly higher than the response of a similar group of mice to a first injection of red cells.

The response of the allogeneic chimæras to a third injection was indistinguishable from a primary response and was in any case drastically reduced in comparison with either normal mice or syngeneic chimæras.

(*b*) *Passive immunity.* The results of the passive immunity experiment which are summarized in Fig. 2 and Table 2 can be interpreted as follows: the titre of the pooled immune serum was $\log_2 13$ before its injection into the experimental mice. Within 36 h the serum titres of the injected mice were about $\log_2 11$. This drop in titre could be attributed largely to dilution, but perhaps also to retention of antibody in extravascular sites and in part to decay or destruction of the antibody molecules. In normal mice the rate of decline of amount of antibody does not vary significantly after 36 h and follows an exponential curve which defines the half-life as about 5 days. Both groups of irradiated mice show a significantly more prolonged period of accelerated decay than normal mice, but stability is achieved in the syngeneic chimæras during period one (top of Fig. 2) and in period two in the allogeneic chimæras.

Statistical analysis showed that there were no significant differences between the decay rates of antibody in period one taken by itself. During period two, however, the two groups of chimæras differed from each other, the allogeneic having a higher decay rate than the syngeneic chimæras. Further, the allogeneic chimæras had a higher decay rate than did the normal mice. Within period three the decay rates were similar for all groups of mice giving an antibody half-life of almost 5 days.

The results of Garver *et al.*[1] and of Hollingsworth[2] taken in conjunction with the present findings demonstrate that active immunity to red cell antigens can persist in heavily irradiated animals that have received syngeneic bone marrow as a therapeutic measure. The additional information provided by the present findings can be assessed after consideration of the results of the subsidiary experiment on passive immunity, which showed that in normal mice and irradiated animals the biological half-life of mouse anti-sheep-red-cell antibody was about 5 days. This value is similar to that of 4·5 days quoted by Humphrey (personal communication), rather higher than that which can be calculated from the results of Mitchison[7] and lower than the 8 days quoted by Dresser[8]. On the basis of this result, Fig. 1 needs the added interpretation that actively immune normal mice and syngeneic chimæras synthesize antibody during the period from day 20 to day 70, as the rate of decline of amount of antibody (apparently half-life 9 days) is too slow to be accounted for simply by passive loss.

The rate of passive decline when allogeneic bone marrow is injected after irradiation indicates an antibody half-life of 2 days for about 8–10 days, after which it approximate to the normal passive decay rate. It is not possible to say whether synthesis of antibody stops or is reduced in the allogeneic chimæras, but it is possible to say that by 20 days after irradiation and probably less it is continuing at approximately the same (declining) rate as was observed in normal mice and syngeneic chimæras, assuming that the antibody present is qualitatively unchanged.

For the present purpose, immunity may be considered under two headings: (*a*) synthesis of antibody; (*b*) the anamnestic response. The synthesizing component is apparently insensitive to radiation and the injection of bone marrow. The anamnestic component is apparently destroyed by irradiation and injection of allogeneic bone marrow but is maintained, albeit slightly reduced, after irradiation and the injection of syngeneic bone marrow.

The most plausible explanation of the results is "that treatment of severe irradiation injury with bone marrow cells does not supplant the humoral antibody production mechanisms of the host with those of the donor"[1]. This may be extended to cover skin homograft immunity on the basis of the results of Cross *et al.*[9]. The question to decide is, first, whether host cell persistence is likely and, secondly, if host cells do persist, what type of cell is required for the maintenance of immunity as considered here.

Early in the history of the investigation of radiation chimæras Ford and his colleagues[10] showed that damaged host cells could be found dividing in the spleen, thymus,

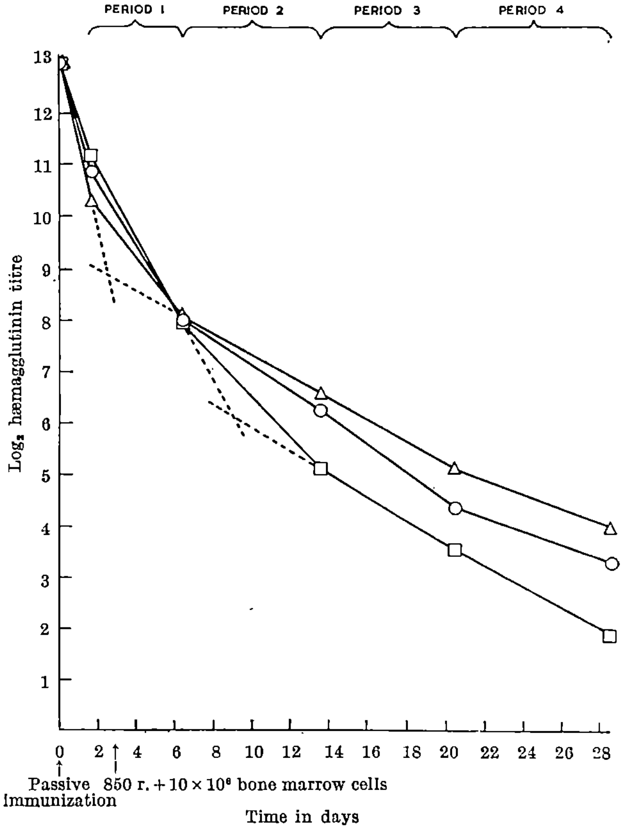

Fig. 2. The hæmagglutinin titres of various kinds of passively immunized *BALB/c* mice in relation to time (normal mice were not irradiated) △, normal mice; ○, *BALB/c→BALB/c* syngeneic chimæras; □, *CBA→BALB/c* allogeneic chimæras

bone marrow and lymph nodes of irradiated animals injected with bone marrow. These cells were found in diminishing numbers with increasing time after irradiation and could only rarely be found after 30 days. Dividing cells present at later times in all hæmatopoietic and lymphoid organs were almost always donor cells. Since then many methods, other than cytological ones, have shown that chimærism established after radiation is often permanent and complete.

The cytological and serological checks on chimærism used in the present experiments, 60 days after irradiation, indicated that the erythropoietic system of the allogeneic chimæras and the dividing cells in the spleens of the immunologically stimulated syngeneic chimæras were donor type. Thus the chimæras the immune response of which is under consideration were typical, but neither the tests performed on them nor the data about chimæras adduced here are sufficient evidence that no host cells were present. All that can be said is that they were not discovered.

The problem can be approached from another aspect. If the immune response observed is a property of the host, which cells are involved and would they be detectable in tests for chimærism ?

The antibody synthesized by the chimæras and by the normal mice during the decline phase of the immune response is likely to have derived largely if not wholly from plasma cells, as few other cells have been shown regularly to synthesize antibody. It is well known that plasma cells appear after irradiation, though it is not clear whether they simply become obvious because other cells have been destroyed and phagocytozed or whether they are produced in response to an immunological stimulus[11]. Nossal[12] maintains that at least some plasma cells have a relatively short functional life and cell division is required to ensure their replacement. If such divisions of host cells occur in order to provide antibody-producing cells, why have they not been seen ? Alternatively, the plasma cells under consideration are long-lived and radiation-resistant. No conclusion can at present be arrived at except to say that the mechanism for the continuation of antibody synthesis may in part survive irradiation, but even if the host cells observable early after irradiation are part of the mechanism, its cellular components cannot be found to divide in appreciable numbers subsequent to 30 days after irradiation. It is tempting to wonder whether the continuation of antibody synthesis becomes a property of the donor cells, which are present in abundance in radiation chimæras, rather than remaining a property of host cells the very existence of which may be a chimæra.

Nossal[12] concludes from an extensive and elegant series of experiments that "the cell type (in resting primarily immunized nodes) capable of responding instantly to antigenic stimulation, and thus presumably carrying specific immunological memory, is a rapidly proliferating primitive lymphocyte". The experiments of Makinodan *et al.*[13] indicate that the D_{37} of the appropriate cells, primitive lymphocytes or not, is 70 r. The dose of radiation used in the present experiments was 850 r. and it must be concluded that very few of the relevant cells could have survived such irradiation. If, however, sufficient cells did survive and, by their active proliferation on antigenic stimulation, 60 days after irradiation, initiated the response to a third injection of sheep cells observed in the syngeneic chimæras, why were not their divisions observed ?

The allogeneic chimæra proved to be incapable of effecting a recognizable anamnestic response which could either mean that the relevant host cells had been destroyed by a graft-versus-host reaction or that part of the immunological system necessary for the receipt and processing of antigenic material fails to develop. The authors incline to this latter view and are attempting to disprove it.

Over all, the evidence for the persistence of sufficient host cells to maintain immunity in chimæras as observed is not good. The alternative hypothesis, that it is the donor cells which do the work, requires that the capacity to do so is in some way transferred from the irradiated host cells to the incoming donor tissues. This possibility will be considered more extensively elsewhere. It must suffice to say here that we can find no evidence, after irradiation of immune mice, for massive release of antigen, complete in that it simulates injection of sheep red cells (unpublished observations). The finding discussed by Campbell[14], that immunity to protein antigens may be maintained by the persistence of haptenic polypeptides strongly bound to low molecular weight RNA, which, it is not inconceivable, could be liberated on irradiation, is perhaps relevant. Further, there is an accumulation of largely circumstantial evidence that transfer of immunological information between cells is a very real possibility[15-22].

The problem raised here from the very artificial situation existing in radiation chimæras relates to the general problem of the persistence of immunological information in immunized mice. However, until a clear description of the cells involved in an immune response can be made any approach is bound to have a large speculative component. This matter has been thoroughly discussed by Humphrey[23] and it should be noted that he says "we cannot rule out the possibility that the precursors of antibody-producing cells never actually ingest antigen directly, but are stimulated by nucleoproteins, derived from phagocytic cells".

(II) By Thymectomized Syngeneic Radiation Chimæras

By A. MARJORIE CROSS, ELIZABETH LEUCHARS and DR. A. J. S. DAVIES

IT has been shown[1] that mice which were immunized to sheep erythrocytes, before exposure to a potentially lethal dose of irradiation followed by syngeneic bone marrow therapy, continued to synthesize hæmagglutinins after irradiation. When a further injection of sheep erythrocytes was given there was a weak but significant anamnestic response. The data presented here concern similar experiments in which immunized mice were thymectomized before irradiation and syngeneic bone marrow therapy. It has been shown[2] that such animals are unable to respond to a primary challenge with certain antigens and it was considered to be of interest to determine whether they would respond to secondary challenge with such antigens. In a further experiment bone marrow was taken from neonatally thymectomized donors to see whether immunological incompetence of the donor would affect the result obtained.

Male mice of the *CBA* strain were used as irradiated hosts and as donors of bone marrow cells. In addition skin was taken for grafting from *Ak* mice which have the same *H*-2 antigens as *CBA*, and *C57BL* mice which have different *H*-2 antigens. All mice were from highly inbred Chester Beatty strains.

Thymectomy or sham operation was performed as described by Miller[3]. At the end of the experiment all thymectomized mice were checked for thymic remnants, none of which was found. The radiation dose used was 850 r. After irradiation the mice were injected with 5 million syngeneic bone marrow cells.

Mice were immunized with *Ak* skin grafts using the method of Billingham and Medawar[4] and by intraperitoneal injections of 0·2 ml. of a 20 per cent suspension of sheep erythrocytes in Alsever's solution. The time schedule is shown in Table 1. Hæmagglutinins were estimated as before[1].

The survival times of *Ak* and *C57BL* skin grafts on normal mice are shown in Table 2. *Ak* skin grafts on pre-immunized mice showed an accelerated second-set type of rejection. The skin grafting results in the thymectomized irradiated mice are shown in Table 3. Neither the thymectomized nor the irradiated control groups showed a typical second-set rejection, but the mean survival time on irradiated mice was significantly shorter than that of a first graft of *Ak* skin ($P < 0·01$). The mean survival time on pre-immunized thymectomized mice (17·2 days) did not differ significantly from the mean survival time for a first graft of *Ak* skin on thymectomized control mice (16·6 days). In the experimental groups most of the *Ak* grafts showed longer survival times and were rejected between 20 and 50 days. However, the number of grafts surviving until 50 days (9 out of 64) is considerably less than that found by Miller, Doak and Cross[2] in thymectomized, irradiated mice which had not been pre-immunized (36 out of 39).

A surprising finding was that the thymectomized irradiated mice which had been pre-immunized to *Ak* also rejected their *C57BL* skin grafts. However, the specificity of the immunization to *Ak* antigens was shown by the fact that, although the *C57BL* grafts were more foreign to the *CBA* hosts than the *Ak* grafts, their survival time was longer than that of the *Ak*. Twice as many *C57BL* as *Ak* grafts were still intact at 50 days. In view of this finding experiments were carried out with normal mice to see whether immunization with *Ak* skin had any effect on the survival of subsequent *C57BL* skin grafts (Table 2). It was found that there was in fact a highly significant reduction in the mean survival time of the *C57BL* grafts ($P < 0·001$), indicating that mice immunized to *Ak* had also been made immune to some of the antigens possessed by *C57BL*.

The results of the hæmagglutinin titrations are shown in Table 4. It can be seen that the titres of antibody remaining from the immunization procedure were similar in all groups. Normal pre-immunized mice showed a $\log_2$ titre of 11·71 at the time at which the experimental groups were irradiated. Experiments with mice passively immunized against sheep erythrocytes[1] indicated a half-life of 4–5 days for these antibodies. If antibody synthesis had been completely stopped in the experimental groups by thymectomy and irradiation, antibodies should not have been detectable by day 60.

After a further injection of sheep erythrocytes the mean titres of all groups showed an increase which was statistically significant. In only 3 of the 31 individual mice in experimental group I, and 3 of the 15 mice in experimental group II, was the increase in titre less than fourfold.

The increase in titre is shown graphically in Fig. 1. The thymectomized control group showed a rapid increase to day 5, similar to that in normal mice. The increase in the irradiated controls was slower, and in these mice the survival times of skin grafts were longer than in the other controls. The increase in titre of the two experimental groups was very similar although the starting titre of the group given bone marrow from neonatally thymectomized donors was considerably lower. In thymectomized irradiated mice which had not been pre-immunized the mean titre had increased to only $\log_2$ 0·25 by day 7 (ref. 2).

It is now clear that the immunological response of thymectomized *CBA* syngeneic radiation chimæras to a variety of primary antigenic stimuli is reduced or absent[2]. The results of the present experiments show that established immunity can persist despite removal of the thymus and irradiation. The responses are, however, weak and can only be defined as secondary by virtue of the fact that control animals show no primary response.

Interpretation of the results of the present experiments is complicated because the control group of mice which were simply thymectomized showed no secondary response to skin grafts, although their secondary response to sheep erythrocytes was enhanced. Thymectomy of the adult

Table 1. EXPERIMENTAL SCHEDULE

	Day 0	Day 8	Day 12	Day 15	Day 20	Day 28			
Group						Day 0	Day 28	Day 60	Day 65 Day 67 Day 69
Normal	First graft of *Ak* skin	First injection of sheep erythrocytes	Second graft of *Ak* skin	Second injection of sheep erythrocytes	—	—	*Ak* and *C57BL* skin grafts	Titration of residual hæmagglutinins Injection of sheep erythrocytes	Titration of hæmagglutinins
Control I					Sham thymectomy	Irradiation and syngeneic bone marrow			
Control II					Thymectomy	Sham irradiation and syngeneic bone marrow			
Experimental I					Thymectomy	Irradiation and syngeneic bone marrow			
Experimental II					Thymectomy	Irradiation and syngeneic bone marrow from neonatally thymectomized donors			

Table 2. SKIN GRAFT SURVIVAL TIMES IN NORMAL *CBA* MICE

Treatment	Donor skin	No. of mice in group	No. of mice showing skin-graft survival for: less than 20 days	20-30 days	M.S.T. ± S.D.
Non-immunized	*Ak*	20	6	14	21·7 ± 2·50
	C57BL	11	11	0	14·6 ± 2·13
Immunized with *Ak* skin	*Ak*	10	10	0	9·9 ± 0·94
Immunized with *Ak* skin	*C57BL*	9	9	0	10·5 ± 2·77

Table 3. Skin Graft Survival Times in *CBA* Mice Pre-immunized with *Ak* Skin

Treatment	Donor skin	No. of mice in group	No. of mice showing skin-graft survival for:			M.S.T. ± *S.D.*
			< 20 days	20–50 days	> 50 days	
Control I Sham-thymectomized 850 r. and syngeneic bone marrow	*Ak* *C57BL*	20	18 20	2 0	0 0	19·1 ±2·3 18·3 ±0·33
Control II Thymectomized sham-irradiated syngeneic bone marrow	*Ak* *C57BL*	20	20 20	0 0	0 0	17·2 ±1·16 16·97 ±0·21

* Mean survival time for grafts rejected before 50 days.

appears to have little effect on immune responses, except those to closely related antigens[5,6]. It does, however, result in a diminution of the number of lymphocytes in the peripheral blood, and it has been suggested that this is due to sequestration of lymphocytes in the lymph nodes (Gowans, personal communication). If this is the case it is possible that an insufficient number of cells would be released on second challenge with antigen to cause accelerated rejection of skin grafts, although the production of antibodies, when cell release is not necessary, would be unaffected. The response of thymectomized mice to a second skin homograft, then, would be slow and indistinguishable in timing from the primary response, but the lymph nodes would contain cells committed to respond to the antigens concerned. This point is at present being investigated in collaboration with Dr. P. Dukor.

The results with thymectomized and irradiated mice indicate that once the primary response has been initiated the thymus is no longer necessary for: (*a*) continuation of the primary response—otherwise synthesis of hæmagglutinins would not have continued; (*b*) initiation of a secondary response.

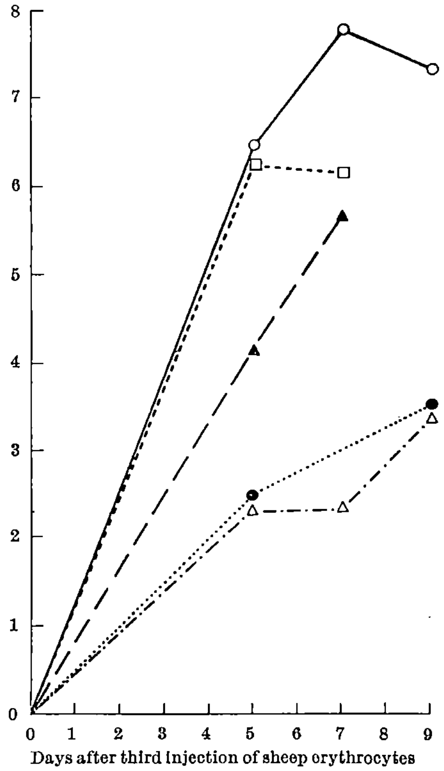

Fig. 1. Increase in hæmagglutinin titre after a third injection of sheep erythrocytes 80 days after the first

Table 4. Hæmagglutinin Titres in Mice Pre-immunized to Sheep Erythrocytes after a further Injection of Antigen 80 Days after the First

Treatment	Mean $\log_2$ titres and *S.D.* at following times after antigen injection			
	Day 0	Day 5	Day 7	Day 9
Normal	5·87 ±0·35	12·12 ±0·65	12·0 ±0·5	
Control I 850 r. and syngeneic bone marrow	5·67 ±1·28	9·83 ±1·75	11·33 ±3·3	
Control II Thymectomized, sham irradiated, and syngeneic bone marrow	6·8 ±1·211	13·27 ±1·977	14·53 ±1·154	14·13 ±2·25
Experimental I Thymectomized, 850 r. and syngeneic bone marrow	7·16 ±3·037	9·471 ±3·027	9·50 ±2·693	10·53 ±3·54
Experimental II Thymectomized, 850 r. and syngeneic bone marrow from neonatally thymectomized donors	4·331 ±2·463	6·801 ±2·033		7·867 ±3·759

The secondary response is weak in thymectomized syngeneic chimæras as it is in allogeneic chimæras. Both groups show lymphoid atrophy and weakening of response may be due to faults in the afferent or efferent immunological pathways.

The secondary response in the experimental mice survives the effects not only of thymectomy but also of irradiation. Davies *et al.*[1] showed that in syngeneic radiation chimæras the secondary response to antigens encountered prior to irradiation was not lost. They considered whether this response was mediated by surviving host cells or by activation of injected bone marrow cells, either directly by antigen, or indirectly by transfer of some kind of 'information'. The same arguments apply to thymectomized irradiated mice, but a further interesting point arises from the present results. The thymectomized mice of experimental group II were injected, after irradiation, with bone marrow from neonatally thymectomized mice. The cells of the donors *in situ* could react only weakly or not at all to sheep erythrocytes or skin homografts and are unlikely to have had the ability to be sensitized with antigen when transferred to a new host. If transfer of information does occur, the cells capable of picking it up are present in the bone marrow of neonatally thymectomized as well as normal mice.

ENTHALPY OF BINDING OF AROMATIC AMINES TO BOVINE SERUM ALBUMIN

By M. R. V. SAHYUN

National Cancer Institute, Bethesda, Maryland

SERUM albumin is physiologically important for its transport function[1]. It binds numerous otherwise insoluble or only slightly soluble substances and transports them to the site of their physiological activity. Laurence[2] has interpreted this binding in terms of absorption of the small molecule on the surface of the albumin molecule. In order to gain further insight into the mechanism by which albumin effects this binding, other workers[3,4] have attempted to characterize the process in terms of thermodynamic parameters derived from the binding dissociation equilibrium at two temperatures. Both groups of workers concluded that two types of sites were involved in the binding of a variety of molecules, both neutral and ionic. Laurence[2], however, required only one type of binding site in his interpretation. Before mechanistic inferences could be induced from the thermodynamic data the latter had to be corrected for the fact that the equilibrium is between states in which the bound molecules possess differing numbers of degrees of freedom[4,5]. These corrections were actually derived from theoretical approximations and introduced an additional uncertainty into the data. The present work was undertaken to obtain meaningful thermodynamic data without the uncertainty inherent in the comparison of the bound state with the dissolved state.

One possible approach would correct the thermodynamic parameters derived from the dissociation equilibrium by the corresponding empirical quantities describing the dissolved state. The thermodynamic parameters for solution of solids are determined, usually, from solubility data, that is, by comparing the dissolved state with the crystalline state of the compound. Consequently, this methodology simplifies the comparison of the bound and crystalline states of the bound compound. It parallels the approach of solution thermodynamics; indeed, Everett[6] has pointed out the analogy between the thermodynamic treatments of solution and adsorption on theoretical grounds. The bound molecules should possess no rotational freedom either in the bound or crystalline state, so no disorientation entropy correction is necessary in comparing the bound and crystalline states.

The experimental method contingent on the above approach was as follows. Six aromatic amines were selected for investigation; *p*-aminobiphenyl, *p*-phenylacetanilide, *N*-acetyl-2-aminofluorene, *p,p'-bis*(*N,N*-dimethylaminophenyl)methane and *p,p'-bis*(*N,N*-dimethylamino)benzophenone (Michler's 'ketone') are all crystalline solids which are easily assayable by ultra-violet spectrophotometry. The pertinent data are given in Table 1. The solubility of each of these compounds in aqueous bovine serum albumin buffered at *p*H 7·5 and 10·5 with phosphate and carbonate buffers, respectively, was determined by shaking at 9·0 ± 0·2° C, 17·0 ± 0·5° C and 25·0 ± 0·5° C for 16 h. Experiments showed shorter shaking times to be inadequate to maximize amine solubilization; longer times resulted in no further change in the extent of the solubilization. Rapid filtration of the mixtures, during which the solution temperatures did not change, gave solid-free solutions. These were analysed by taking their spectra at appropriate dilutions against the buffered protein solutions as blanks. No change in the spectra of the protein or the compounds was noted. The amount of amine in solution was then the sum of the amine dissolved in the buffer solution independently of the protein and that bound to the albumin. The former quantity was assumed to be equal to the solubility of the amine in the buffer analogously determined in the absence of protein. The amount of amine bound to protein was then divided by the albumin concentration (based on a molecular weight of 64,500 (ref. 1)) to give a ratio, K, which was constant for 0·5, 2·5, 5·0 and 7·5 per cent bovine serum albumin solution at each temperature and *p*H. These data are reported in Table 2. It is interesting that the binding power of the serum albumin, measured in terms of K, is higher in solutions of higher *p*H; this result apparently contradicts the observation of Klotz[7].

Table 1

Compound	Melting point (°C)	Absorption maximum (mμ)	ε
p-Aminobiphenyl	52–53	271	$1·9 \times 10^4$
p-Phenylacetanilide	177–178	268	$2·5 \times 10^4$
2-Aminofluorene	129–130	278	$1·5 \times 10^4$
N-Acetyl-2-aminofluorene	203–205	276	$2·5 \times 10^4$

	10·5	0·125 ± 0·004	0·26 ± 0·02	0·33 ± 0·02

From the change in K with temperature it was possible to calculate an enthalpy change ΔH, supposedly characteristic of the binding process for each temperature increment. These parameters are reported in Table 3. Most significantly, the observed enthalpies over the lower temperature increment appear to be larger than those for the higher one by, on the average, 11 ± 4 kcal/mole. Despite the uncertainties in the values of ΔH, this difference is statistically real. The melting-points of the compounds indicate that the temperature variation of the activity of the solid state, a, is negligible (< ± 3 per cent) according to the usual approximation[8]:

$$R \ln a = \Delta S_f \ln(T/T_m)$$

where ΔS_f is the entropy of fusion at the melting-point, T is the temperature at which the activity is a, and T_m is the melting-point of the compound. Therefore, the source of the variation of enthalpy change with temperature must lie in the character of the bound state.

Table 3. ENTHALPY OF BINDING BY BOVINE SERUM ALBUMIN

	pH	ΔH (kcal/mole) at: 9–17° C	17–25° C
p-Aminobiphenyl	7·5	14 ± 6	4 ± 4
	10·5	17 ± 7	−1 ± 2
p-Phenylacetanilide	7·5	10 ± 2	4 ± 4
	10·5	10 ± 6	−2 ± 6

	10·5	6 ± 3	2 ± 4
p,p′-*bis*(*N*,*N*-Dimethylaminophenyl)methane	7·5	13 ± 4	2 ± 2
	10·5	17 ± 4	2 ± 3
p,p′-*bis*(*N*,*N*-Dimethylamino)benzophenone	7·5	20 ± 5	6 ± 6
	10·5	16 ± 3	5 ± 3

In the description of the bound state, two types of binding sites have been postulated[3,4] (*vide supra*). If these two types are each characterized by different thermodynamic parameters, then that on which the binding process has a larger ΔH value will become more important with increasing temperature. The enthalpy change calculated as above will then appear to increase. Exactly the opposite effect has actually been observed. The temperature dependence of the enthalpy change cannot reasonably be attributed to destruction of the binding sites by thermal denaturation involving gross changes in the structure, for example, helix-coil transformations, either. The optical rotation of bovine serum albumin at temperatures of 0°–40° C does not support such a speculation[9]. If a change in protein structure is involved in the apparent temperature dependence of enthalpy, it is something more subtle. Yet it is realistic to assume that the enthalpy temperature dependence is an artifice generated by temperature dependence of the relation of the activity of the bound amine to K. From Laurence's[2] absorption model, this relationship should be a function of the active surface area of the albumin molecule available for binding.

Weber[10] has demonstrated reversible thermal dissociation of the albumin into sub-units. Such dissociation could either (*a*) generate additional active surface area for binding, or (*b*) destroy the molecular geometry necessary for binding. The observations obtained here could then be explained in terms of this dissociation hypothesis by postulating the generation of greater binding area between 9° C and 17° C than between 17° C and 25° C (mechanism *a*), by greater destruction of active sites between 17° C and 25° C than between 9° C and 17° C (mechanism *b*), or by a combination of these mechanisms. Intuitively, one expects a small positive ΔH between the absorbed and crystalline states. The experimental values obtained at the higher temperature range therefore would seem less likely to be artificial than those at the lower range. On these grounds, mechanism *a* is more favourable than mechanism *b*; however, a combination of mechanisms *a* and *b*, implying an artificiality of the values at both temperature ranges, is certainly not excluded. As an alkaline medium enhances dissociation of serum albumin[10], the increased binding at higher pH is in accord with this interpretation.

An ambiguity as to the exact origin of the apparent temperature dependence of ΔH, however, remains. The thermodynamic parameters, by themselves, are of little diagnostic value in elucidating the adsorption mechanism, as the apparent temperature dependence of binding may not characterize the binding process *per se*. The temperature-dependence of the extent of binding irrespective of origin is significant, however; the physiological consequences, in terms of temperature-dependence of transport phenomena, for example, appear to be unexplored.

This work was carried out in the laboratory of Dr. W. C. Hueper, chief of the Environmental Cancer Section.

DIRECT DEMONSTRATION OF REAGIN ACTIVITY IN PURIFIED γ_{1A}-GLOBULIN

By J.-P. VAERMAN, WILLIAM EPSTEIN and PROF. HUGH FUDENBERG
Department of Medicine, University of California School of Medicine, San Francisco
and KIMISHIGE ISHIZAKA*
Children's Asthma Research Institute and Hospital, Denver, Colorado

ALTHOUGH many precipitating and agglutinating antibodies have been demonstrated in isolated, purified human 7 *S* (γ_{ss}, γ_2) and 19 *S* (γ_{1M}) immunoglobulins[1], antibody activity in the third class of human immunoglobulins (γ_{1A}-globulins) has been reported only recently[2–5]. Indirect evidence suggests that reagins, the spontaneously produced skin-sensitizing antibodies found in the serum of allergic human subjects, are present in the γ_{1A}-globulin. This evidence consists of the presence of skin-sensitizing activity in impure immune globulin preparations rich in γ_{1A}-globulin[6], the inhibition of reaginic activity by local injection of γ_{1A}-globulin at the sensitized site[7], the inhibition of positive sensitization reactions by addition of anti-γ_{1A} antisera to the sera or fractions under investigation[8], and the fixation of ragweed antigen labelled with iodine-131 after immunoelectrophoresis[9]. However, since "reagin still represents a nebulous concept to many immunologists, some doubting the legitimacy of its classification as an antibody"[10], attempts at direct demonstration of reagin activity in purified γ_{1A}-globulin seemed warranted.

The γ_{1A}, γ_{ss} and γ_{1M}-globulin fractions of the serum of three persons highly allergic to ragweed but not allergic to *Aspergillus* were isolated and purified by a slight modification of a previously described method[11]. Each γ_{1A}-preparation gave one band when tested with anti-human serum and unispecific anti-γ_{1A} antisera by immunoelectrophoretic and gel-diffusion techniques, and did not precipitate with antisera specific for λ_{ss} and γ_{1M} globulins (Fig. 1). An 0·05 ml. sample of each of the purified γ_{ss}, γ_{1M} and γ_{1A}-globulin preparations from each serum was injected intradermally into three normal recipients, and the test sites were challenged 24 h later by either scratch test or intradermal injection of test antigens[12]. All sites challenged with the control *Aspergillus* extract were negative. When challenged with 2 protein nitrogen units (PNU) of ragweed extract, all sites of injections of γ_{1M} and γ_{ss} fractions, as well as of buffered saline (control), were negative, whereas the sites injected with γ_{1A}-globulin gave strongly positive reactions (Fig. 2). As little as 0·05 μg N of the γ_{1A} of one subject produced positive Prausnitz-Küstner (P-K) reactions (8 mm diameter weal and 35-mm diameter erythema) when challenged similarly by intradermal injection of ragweed extract; 0·017 mg N of the γ_{1A} of another donor produced positive reactions

---

* Parts of this work were carried out while one of us (K. I.) was visiting assistant professor, Department of Medicine (Hæmatology Unit), University of California School of Medicine.

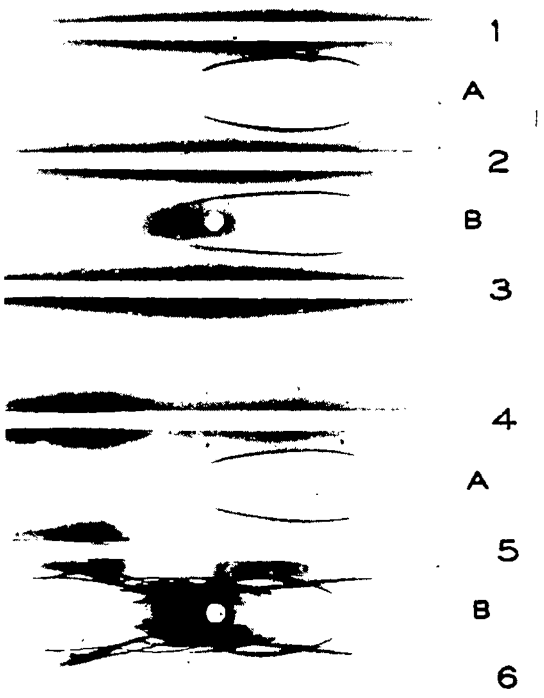

Fig. 1. Immunoelectrophoretic pattern of γ_{1A}-preparations. Numbers indicate antiserum troughs containing anti-human γ_{1A} (1, 2 and 3) and anti-whole human serum (4, 5 and 6). Letters indicate antigen wells containing (A) γ_{1A} from allergic serum and (B) whole serum

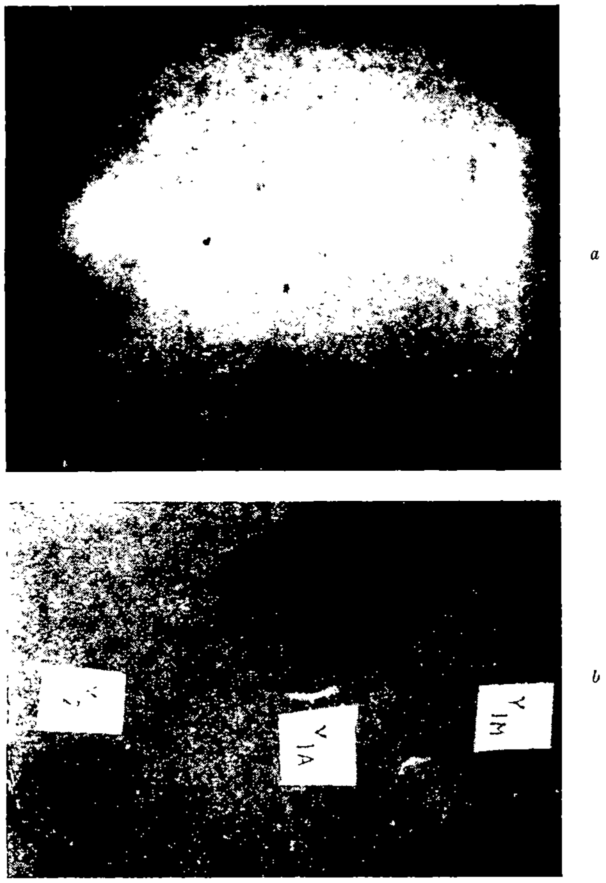

Fig. 2. a, Sites of injection of purified immunoglobulin (γ_{1A}) preparations, showing skin reactions (Prausnitz-Küstner) to ragweed extract (positive, left side) and to *Aspergillus* extract (negative, right side); b shows reactions with ragweed extract that were positive with purified (γ_{1A}) and negative with (γ_2) and (γ_{1M})

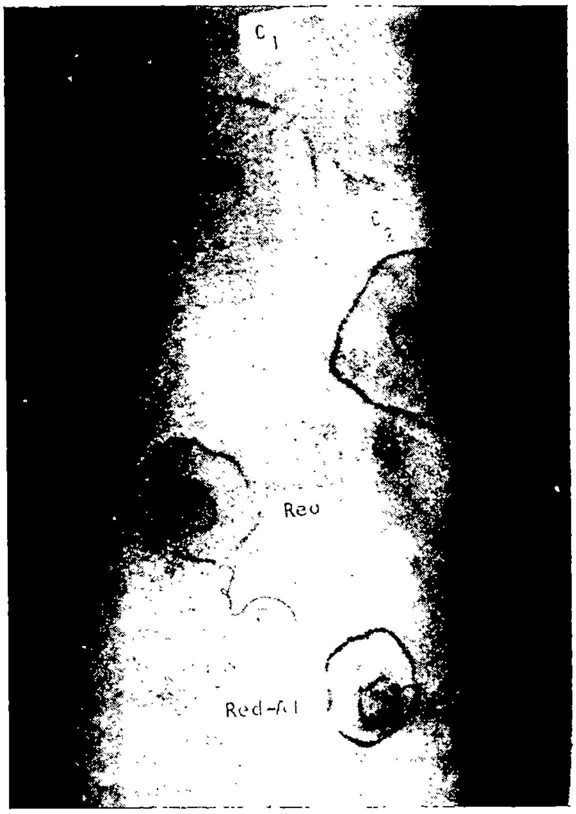

Fig. 3. Skin reactions (Prausnitz-Küstner) to control (C_1, 0·14 μg N. C_2, 0·07 μg N), reduced (Red) and reduced alkylated (*Red-A1*) (0·7 μg N) γ_{1A}-globulin preparations containing reagin to ragweed. Definite erythema and weal reactions to the untreated (control) γ_{1A}-preparations, not clearly visible in the photograph, were present

by scratch test in three normal recipients (7–13 mm weal and 24–46 mm erythema).

Results of additional experiments also supported the conclusion that the anti-ragweed reagin in the sera of the three allergic subjects were γ_{1A}-globulins. (1) Reagin to ragweed was demonstrated by P-K reaction with concentrated parotid saliva (rich in γ_{1A}-globulin and without detectable 7 S γ-globulin[13–15]) from the three allergic persons. The concentrated salivas contained 1 mg/ml. of γ_{1A}, but were devoid of detectable γ_{ss}-globulin by immunoelectrophoresis. (2) In fractions obtained by 'Sephadex G-200' gel-filtration of the sera from the three allergic donors, γ_{1A}-globulin localization and reagin activity were parallel. Reagin and γ_{1A} were eluted from the 'Sephadex' columns simultaneously and appeared before antibodies of the γ_{ss} (γ_2) type, although there was considerable overlap[8,16]. (3) As with whole sera, reaginic activity disappeared when the γ_{1A}-preparations were exposed to heat (56° C for 4 h).

In further experiments, the γ_{1A}-globulin fraction of a reaginic serum was treated with 0·1 M mercaptoethanol for 4 h at room temperature at pH 8·0. One portion of the reduced protein was then dialysed against borate-buffered saline; another was dialysed against iodoacetate (0·02 M) for 24 h and against borate-buffered saline for another 48 h. The original γ_{1A}-fraction (0·05–0·07 μg N), the reduced material (0·7 μg N), and the reduced and alkylated preparation (0·7 μg N) were injected intradermally into a normal subject. When the sites of injection were challenged by intradermal injection of 2 PNU of ragweed pollen extract, the original γ_{1A}-globulin fraction produced a definite erythema and weal reaction (Fig. 3), the reduced material (without alkylation) gave a ± erythema (no weal), and the reduced and alkylated material gave essentially no reaction. Similar results were obtained on reduction-alkylation of the γ_{1A} of the other allergic donors.

These observations demonstrate that 'spontaneously-induced' reaginic antibodies are present in purified γ_{1A}-globulin; however, the possibility that reagins to at least some allergens may also be present in the γ_{ss} (γ_2) or γ_{1M} globulins of some individuals (especially in individuals deliberately immunized or 'desensitized' to specific allergens) is not excluded[9,16]. It is evident that the reaginic activity of the pure γ_{1A}-globulin fraction of an allergic serum, like that of the whole serum[17], is inactivated by reduction of disulphide bonds. This procedure has been shown to split the disulphide bonds of a 9·55 γ_{1A}-myeloma protein[18]. In contrast, there is retention of activity when γ_{ss} (γ_2)-globulin antibodies are treated similarly[19,20]. Results published elsewhere indicate that polymer-type heterogeneity exists in the γ_{1A}-globulin of single individuals[21]. On analytical ultracentrifugation of one of the purified γ_{1A}-globulins with reagenic activity, similar heterogeneity was noted, in that two peaks (6·7 *S*, 91 per cent; 9·7 *S*, 9 per cent) were present. Experiments designed to localize reagin activity to the 6·7 or 9·7 γ_{1A}-globulin of allergic individuals are currently in progress.

This work was supported by contract *Nonr*–3656(12) *NR* 105–308 between the Office of Naval Research, Department of the Navy, and the University of California Medical Center, San Francisco; U.S. Public Health Service grants *H*–5997 and *A*1–04985; and funds allocated by the Committee on Research, University of California School of Medicine, San Francisco, California.

A preliminary report of these experiments has been presented elsewhere[22].

SOME SIMILARITIES BETWEEN A VIRAL INHIBITOR OF PLANT ORIGIN AND CHICK INTERFERON

By DR. K. H. FANTES and C. F. O'NEILL

Virus Unit, Glaxo Laboratories Ltd., Sefton Park, Stoke Poges, Bucks

INTERFERONS have been produced in mammalian and avian cells of a great variety.

Delbruck and Luria[1,2] have described interference in *E. coli* between ultra-violet-inactivated bacteriophage and live phage of the same or a different variety, and Mercer and Mills[3] have produced an interferon-like substance in *Pseudomonas aeruginosa* on interaction with inactivated bacteriophage *Pc*.

Viral interference in plants has recently been reviewed by Rageti[4] and by Atanasoff[5], and properties of antiviral substances of plant origin have been described in the past few years by several authors[4,6–9]. The material isolated by Ragetli and Weintraub from apparently healthy carnation plants seemed to possess such marked similarities to chick interferon that we decided to examine these in some more detail. The few properties mentioned of the substance obtained by Loebenstein and Ross[8], after infecting *Datura stramonium* plants with tobacco mosaic virus, also resembled those of chick interferon, but the material produced by Sela and colleagues[9] with tobacco mosaic virus in *Nicotiana glutinosa* L. plants appeared to be entirely different.

The known properties of the antiviral carnation factor of Ragetli and Weintraub and those of chick interferon are summarized in Table 1.

Ragetli and Weintraub[7] subjected their purified carnation factor to a number of chemical reactions to ascertain which chemical groups were essential for antiviral activity. We applied the same reactions to partly purified chick interferon (material before the DEAE chromatography step)[17], diluted to about 200 interferon units (chick embryo fibroblasts/Semliki Forest virus system) and 50 µg protein[24] per ml. The results obtained by Ragetli and Weintraub[7] with carnation factor are compared with our chick interferon results in Table 2. For all the experiments mentioned in Tables 2 and 3, reagent control experiments without interferon were run in parallel to make sure that no cell toxicity resulted from the treatments. Interferon control experiments were also always carried out; in these, interferon was subjected to the

Table 1. PROPERTIES OF CARNATION FACTOR AND CHICK INTERFERON

	Carnation factor	Chick interferon
Chemical nature	Protein (refs. 4, 6, 7)	Protein (refs. 10–12)
Molecular weight	At least 10,000 (ref. 4)	13,000–38,000 (refs. 12–14, 32)
Sedimentation constant	1·4 (ref. 4)	1·9–3·06 (refs. 12–15)
Precipitated by ammonium sulphate at	50% saturation (ref. 4)	60% saturation (ref. 11)
Heat stability	Stable at 60°, gradual inactivation at higher temperatures (ref. 7)	Similar (refs. 12, 13, 16)
Behaviour towards DEAE-cellulose	Not absorbed at *p*H 7·8 (ref. 6)	Similar (ref. 17)
Behaviour towards *CM*-cellulose	Is adsorbed at *p*H 6·0 and eluted by raising *p*H and ionic concentration	Similar (refs. 12, 17)
Antiviral spectrum	Active against wide variety of viruses and also against viral nucleic acid (refs. 4, 7)	Similar (refs. 10, 18, 19) 39)
Mode of antiviral action	Indirect, via the host (ref. 4)	Similar (refs. 10, 36)
Optimum application time for antiviral activity	Before or with virus, not after (ref. 4)	Similar (refs. 10, 18, 36,
Species specificity	Activity is influenced by the species of the host cell (ref. 4)	Similar (refs. 20, 21, 35)
Effect of EDTA on activity	None (ref. 7)	None (ref. 22)
RNase-activity	None (ref. 7)	None (ref. 17)
Sugar content	None (ref. 4)	Trace carbohydrate (ref. 12)
Electrical charge	Neutral (ref. 4)	Slightly basic (refs. 11, 12) Slightly acidic (refs. 14, 23)
Effect of papain on activity	None (ref. 7)	None (ref. 11) Near total inactivation (refs. 12, 22)
Effect of trypsin on activity	None (ref. 7)	Partial inactivation (refs. 10, 12)
Effect of leucine aminopeptidase on activity	None (ref. 7)	None (ref. 12)
Effect of carboxypeptidase on activity	None (ref. 7)	None (ref. 12)

ANNUAL REVIEW OF ASTRONOMY AND ASTROPHYSICS

Editors: L. Goldberg, A. J. Deutsch, D. R. Layzer

Editorial Committee: R. Bracewell, G. Burbidge, L. Goldberg, N. U. Mayall, M. Schmidt, H. C. Urey

Contents *approx.* 466 *pages*

Radio Emission from Jupiter, James W. Warick
The RR Lyrae Stars, George W. Preston
The Dynamics of Star Clusters, Richard W. Michie
The Moon, Ralph B. Baldwin
Planetary Nebulae, Donald E. Osterbrock
Isotope Chronology of Meteorites, J. Zähringer
Interplanetary Debris near the Earth, Gerald S. Hawkins
Photosensitive Detectors, William A. Baum
Nonthermal Radio Frequency Radiation from the Galaxy, B. Y. Mills
The O Associations in the Solar Neighborhood, Adriaan Blaauw
Supernovae and Supernova Remnants, R. Minkowski
Some Statistical Properties of Comets with Plasma Tails, D. Antrack, L. Biermann, Rh. Lüst
The Structure of the Solar Chromosphere, B. E. J. Pagel
The Atmospheres of the Magnetic and Metallic-Line Stars, Wallace L. W. Sargent
Solar Flares, A. B. Severny
Receivers for Cosmic Radio Waves, B. J. Robinson
Formation of Stars and Galaxies: Unified Hypotheses, David R. Layzer

DO SCIENTISTS NEED A COMPREHENSIVE INDEX TO ALL OF SCIENCE?

When we asked scientists this question recently, most of them replied yes — a few said no. If you are among the few who are perfectly satisfied with the "selective" approach of conventional indexing systems, stop right here. However, if you, along with the majority, feel that improved methods and comprehensiveness are needed in information retrieval and dissemination, read on.

Every research scientist has, on one occasion or another, been stumped by the complex problems of searching the scientific literature. Today's search requirements are hobbled by the limitations of traditionally organized indexing systems.

At the Institute for Scientific Information, we have tested and developed a new dimension in indexing. To this we have added comprehensive coverage, resulting in a unique tool for information discovery. We call it Science Citation Index.

The Science Citation Index instantly identifies the most recent publications referring to a particular work since its publication. The Science Citation Index provides the scientist with an improved, novel starting point: the specific paper or book of a specific author . . . and from there the searcher is brought forward in time to current papers relating to the earlier work.

Revolutionary? Invaluable? We think so and we think you will too after you've had an opportunity to review descriptive material on this new technique. Write us now and we'll send details by return mail —without obligation, of course.

ANIMAL NUTRITION

(SECOND EDITION)

Cyril Tyler

The new edition of this well-known book has been thoroughly revised and brought up to date. It deals with the basic principles of animal nutrition and will provide both a general knowledge of the subject for the agriculturist and an excellent introduction and background study for the specialist.

192 pages 24 diagrams 28s

THE CHEMICAL CONSTITUTION OF NATURAL FATS

(FOURTH EDITION)

T. P. Hilditch, F.R.S.

and P. N. Williams

The book has been revised as completely as possible in the light of fresh knowledge which has occurred since the third edition was published in 1956. It now includes the fatty acid compositions of nearly 1,500 natural fats, and accounts of the quantitative composition of the glycerides in some 100 natural fats.

THE HISTORY OF THE STUDY OF LANDFORMS

Volume I : Geomorphology Before Davis

Richard J. Chorley,

Antony J. Dunn and

Robert P. Beckinsale

Volume I treats the subjects up to the first important statement of the cycle of erosion by W. M. Davis in 1889, and attempts to identify the most significant currents of geomorphic thought, integrating them into the broader contemporary intellectual frameworks with which they were associated. As well as dealing with such key figures as Werner, De Saussure, Hutton, Playfair, Buckland, Lyell, Agassiz, Ramsay, Dana, Peschel, Powell, Gilbert and Davis, attention is also given to many less important contributions by American, British and Continental workers. With more than 120 half-tone illustrations.

The Dynamic Method in Oceanography. L. M. Fomin

Institute of Oceanography, Academy of Sciences of the U.S.S.R., Moscow

Contents: Theoretical principles of indirect computation of sea currents; accuracy of the dynamic method of computing ocean currents; investigation of the vertical velocity distribution of a wind-driven current in a deep sea using a density model; methods for computing the "zero" surface in the sea; practical procedures for computing currents by the dynamic method; dynamic chart of the sea surface in the Kurile-Kamchatka region of the Pacific ocean. 70s.

Turbidites. A. H. Bouma and A. Brouwer

State Universities of Utrecht and Leyden, The Netherlands

Extract of Contents: The turbidite concept in Britain; turbidite studies in the United States; flysch formations of the northern Apennines; turbidite sediments in the south western Adriatic sea; bibliography of turbidity currents and turbidites. 90s.

Mechanisms of Solid Friction. P. J. Bryant, M. Lavik and G. Salomon

P. J. Bryant and M. Lavik, Midwest Research Institute, Kansas, Missouri; G. Salomon, T.N.O. Institute, Delft

Contents: Surface energy and temperature considerations; ionic solids; lamellar solids; metallic friction; metallic wear. 50s.

Structural Characteristics of Metals. E. P. Polushkin

Formerly Associate Professor of Metallurgy, Stevens Institute of Technology, Hoboken

Contents: Crystalline structure of metals; shapes and arrangement of grains in a metal; solid solutions; eutectics and eutectoids; polishing; etching; metallographic microscope; photomicrography; electron microscopy and other advanced metallographic techniques; microstructure and properties of pure metals. 45s.

Unsaturated Polyesters (structure and properties). Herman V. Boenig

Contents: Historical development; structure of unsaturated polyesters; cross-linking mechanism in polyesters; the cross-linked network; chemistry of polyester compounding; effect of structure of the polyester backbone on properties of the cured products; effect of unsaturated monomers on properties of cured products; structure and flame retardance; polyester coating compositions. 55s.

BRITAIN AND ATOMIC ENERGY: 1939–1945

MARGARET GOWING, *B.Sc.(Econ.), Historian and Archivist, United Kingdom Atomic Energy Authority*

This history of the United Kingdom Atomic Energy Project up to the time the first atomic bombs were dropped on Japan was commissioned by the U.K.A.E.A., and much use has been made of official documents in this the first authoritative account of Britain's part in the development of atomic energy. The book is in three parts: a study of feasibility; the independent work in North America and Britain; and the joint work in North America.

CARBIDES IN NUCLEAR ENERGY

Edited by L. E. RUSSELL, *B.Sc.Tech., Sc.D. (M.I.T.)*
Group Leader Plutonium Ceramics, A.E.R.E. Harwell

The Proceedings of an international symposium on the uses of carbides in nuclear energy held at Harwell in November 1963. The volumes comprise 65 illustrated papers with their discussions, each provided with a bibliography and an abstract in English, French and German. A common general index is included in each volume.

Vol. 1. Phase Diagrams and Physical and Chemical Properties.
Vol. 2. Preparation, Fabrication, Irradiation and Behaviour.

Each about 500 *pp.*, 300 *illus., October* 15*th*, £10 10*s the set*

COMPUTER APPLICATIONS

Edited by ROBERT S. HOLLITCH *and* MILTON M. GUTTERMAN

This report of the Ninth (1962) Symposium, organized at the Illinois Institute of Technology, is a cogent survey for all who are actually using computers to solve problems in business, management, science and engineering. The contributors discuss both "software" and "hardware" applications, including contemporary and experimental programming languages.

224 *pp. Illus.* 56*s*

ATLAS OF THE MOON

VINCENT DE CALLATAŸ

By the same author as the successful Atlas of the Sky, *Atlas of the Moon* gives a detailed, yet readable and easily understood, account of all aspects of the moon, sumptuously illustrated with a wide range of informative photographs and diagrams. With a foreword by Sir Bernard Lovell.
Translated by R. G. Lascelles.
10 × 12½ in., 160 *pp.*, 70*s*

CLIMATOLOGY: AN INTRODUCTION

J. BUCKNELL, *M.Sc., Ph.D., F.R.G.S., Weymouth Training College.*

Provides the ground work in climatology which together with geomorphology forms the basis of most geographical studies. Presentation is straightforward and lucid and much of the work is in diagram form. The major section of the book is based on Professor A. A. Miller's widely accepted method of climatic classification. Questions and exercises are included.
October 29th, 160 *pp.*, 195 *illus.*, 18*s*

MATTER AND METHOD

R. HARRÉ, *B.Phil., Lecturer in the Philosophy of Science, University of Oxford.*

Mr. Harré's new book concerns the scientific thought of the 17th and 18th centuries, notably the corpuscular theory of matter. He enables us to understand what British 18th-century philosophers were so excited about. This evocation of an intellectual climate will interest students both of history and of science.

Stratification and Circulation in the Antillean-Caribbean Basins

PART I: Spreading and Mixing of the Water Types

By GEORG WUST

The first part of a two-part study of the stratification and circulation of currents in the Antillean-Caribbean Basins. Part One, which deals with the geography and temperature of the Caribbean, includes an Atlas of the Basins.

The foreword is by Maurice Ewing, Director, Lamont Geophysical Laboratory.

Part II, which will be a separate book, will be concerned with currents and geochemical determination. It will be Number III in the Vema Research Series.

256 pages, 8¾″×11¾″ £5 5s. net

The Natural Geography of Plants

By H. A. GLEASON and A. CRONQUIST

Although primarily concerned with the plant cover of the continent of North America and of the U.S.A. in particular, the authors frequently cite examples in other parts of the world to illustrate the universality of the principles involved.

One of the important and outstanding features of the volume is its illustrations. The authors have included nearly 200 visual aids which graphically illustrate different kinds of plants, plant communities, plant migration, and general plant and area characteristics. These are so arranged as to illustrate points made in the text and can easily be followed by the reader interested in landscape variations and their geographical occurrence.

conditions summarized in Tables 1–3, but in the absence of the chemical reagents, so as to ensure that any loss of activity was due to the latter and not to damage caused by adverse *p*H or temperature. All samples were thoroughly dialysed against Earle's buffer before assay.

Ragetli and Weintraub[7] concluded from their experiments that an amino-group, probably an ε-amino-group of lysine, is essential for biological activity of their factor. The argument in favour of an ε-amino-group of lysine being involved was based mainly on the different results which were obtained with the two concentrations of acetic anhydride. Since neither acetic anhydride nor benzoylchloride completely abolished antiviral activity, it was further argued that the essential amino-groups were not readily available for acylation; on the other hand, the possibility of groups other than amino groups playing an additional part in the antiviral mechanism could not be dismissed. They, however, think it unlikely that sulphydryl, disulphide or hydroxyl groups are important for the biological action.

Our results obtained with chick interferon again show that an amino-group is needed for biological activity, but this activity is completely destroyed by either acetic anhydride at either level, or by benzoylchloride. Sulphydryl or hydroxyl groups, if present, seem to be, as in the carnation factor, of little importance. (Phenyl isocyanate at *p*H 5·8 gave fluctuating results, even after the buffer concentration was increased to minimize the possibility of an upward *p*H drift.)

One striking difference between the two molecules was revealed by their behaviour towards performic acid. This had no effect on the activity of the carnation factor, but (at the higher level) invariably destroyed the potency of chick interferon. Neither formic acid nor hydrogen peroxide, when used separately under otherwise identical conditions, impaired the biological activity of chick interferon. Performic acid is known to oxidize disulphide bonds[25,40]. In order to get more evidence for the presence of such a bond, we subjected chick interferon to a number of the treatments used in the reductive fission of disulphide links. The results of these and of some other treatments are given in Table 3.

The results show that those reductive treatments known to break disulphide bonds always reduced or abolished interferon activity. Further attempts to inactivate interferon with chemicals that react with sulphydryl groups again failed. Reduced activity observed after treatment with cysteine and bromoacetate[29] together did not lead to greater inactivation than that caused by cysteine alone—support for the view that the chemical attack is directed towards a disulphide and not a sulphydryl group.

An attempt was made to restore antiviral activity lost after 8 h treatment at *p*H 5 with benzyl mercaptan (100 mM), by bubbling air through such a solution for 16 h at room temperature, having first removed the reducing agent by dialysis against phosphate buffer (M/50, *p*H 6·5). No activity was thereby restored; the material possibly behaves like insulin under this treatment[33]. Similar aeration of an untreated interferon solution had no effect on its activity. According to Sun Yu-Kun and Tsou Chen-Lu[29], bromoacetate at *p*H 5 had no effect on sulphydryl groups (of papain), but it attacked the imidazole group of histidine; interferon activity, however, stayed intact at this *p*H and also at *p*H 8·2, at which *p*H sulphydryl groups are methylcarboxylated. Cyanogen bromide at *p*H 2 completely inactivated interferon. Such a reaction was shown by Gross and Witkop[41] to cleave ribonuclease and by Hofmann[31] to cleave the peptide chain of trypsinogen at the carboxyl end of methionine residues. The question whether

Table 2. EFFECT OF SOME REAGENTS ON ANTIVIRAL ACTIVITY OF CARNATION FACTOR AND CHICK INTERFERON

Reagent	Concentration (mM)	*p*H	Duration of reaction (h)	Temperature of reaction (°C)	Residual inhibitor activity (%)		Protein groups primarily attacked (ref. 7)

R° = Room temperature.

a similar reaction occurred in the interferon molecule will not be answered with certainty until sufficiently large amounts of pure chick interferon become available for more detailed investigations. The postulated presence of one or more essential disulphide groups in the molecule is clearly also hypothetical at present, since it is not even known that chick interferon contains any sulphur. No sulphur-containing amino-acid was found in the hydrolysates of the carnation factor[7].

Although chick and other interferons show species specificity, such specificity is not absolute[20,21,34,35]. We therefore investigated whether the carnation factor possessed antiviral activity against Semliki Forest virus in chick embryo fibroblasts, the system used by us for the assay of chick interferon. Several carnation plants (*Dianthus caryophyllus*) were homogenized in the presence of 0·15 M sodium chloride (0·5 v/w), the brei was filtered through coarse sintered glass and the filtrate clarified by low- and high-speed centrifugation as described by Ragetli and Weintraub[6]. The supernatant layer, after dialysis against Earle's buffer, was found to be cytotoxic in the assay system, even at high dilution. Portions of the fluid were therefore purified further by the method of Ragetli and Weintraub[6] and also by the method used by us for chick interferon (without DEAE cellulose chromatography)[17]. Two- to ten-fold concentrates (by volume) of juice, purified by either scheme, were no longer cytotoxic, but they were also unable to protect chick fibroblasts against viral attack.

This failure to protect chick cells was in fact not really surprising. Nevertheless there appear to be many chemical, physical and biological similarities between the plant factor and chick interferon, which make one wonder whether the production of the two materials is stimulated by related agents (viruses, foreign nucleic acids[37]) for similar defence purposes. Although the carnation factor was obtained from apparently healthy plants, it is conceivable that they were carriers of a so far undetected virus. Alternatively, by analogy with animal cells[38] even normal uninfected plant cells might perhaps carry low levels of an interferon-like substance.

On the other hand, there are examples to show that antiviral activity in some plants is induced or increased by viral infection. Loebenstein and Ross[8] have shown that the concentration of an extractable antiviral factor (resembling interferon) in the leaves of *Datura stramonium* was much higher after than before infection with tobacco mosaic virus. Sela *et al.*[9] found that the juice of uninfected *Nicotiana glutinosa* L. leaves contained antiviral activity, but that an additional new antiviral substance was produced when the plants became infected with tobacco mosaic virus. This newly formed substance is a nucleoprotein and differs from chick interferon in its behaviour towards ion-exchange celluloses.

It thus appears that plants contain a number of naturally occurring antiviral substances resembling avian, and probably mammalian, interferons to varying degrees. Atanasoff[5] pointed out that resistance to virus disease in plants has been known for a much longer time than resistance in animals. Plant strains, thus protected, are of great importance, and one cannot but speculate whether the principle underlying that resistance is the same as the more recently discovered interferon-mediated viral immunity of mammalian and avian cells.

We thank Mr. P. J. Mason and Mrs. D. Buckland for carrying out the interferon assays and Dr. I. G. S. Furminger for RNase estimations.

FORMATION OF TRIPLET STATES OF SOLUTES IN THE RADIOLYSIS OF ORGANIC LIQUIDS

By Prof. F. S. DAINTON, F.R.S., Dr. T. J. KEMP and Dr. G. A. SALMON
Department of Physical Chemistry, University of Leeds
AND
Dr. J. P. KEENE
Christie Hospital and Holt Radium Institute, Manchester

WE have investigated the transient absorption spectra produced by short pulses (dose $\simeq$ 6,500 rads in 2 μsec) of 4-MeV electrons incident on dilute solutions, generally about 10^{-2} M in concentration, of naphthalene or benzophenone or diphenyl in various aprotic organic liquids at room temperature using techniques previously described[1]. The results are summarized here.

(1) 9·8 *mM solutions of naphthalene* (*N*). This solute has a singlet ground state and a triplet excited state, N^T, at about 21,000 cm^{-1} higher energy, and can capture

Table 1. TRANSIENT SPECIES IN THE PULSE RADIOLYSIS OF 9·8 mM NAPHTHALENE SOLUTIONS

Species	N^T			$\dot{N}$H		
Solvent	λ_{max} (mμ)	G ε_{max}	Decay half-life (μsec)	λ_{max}	$G \times$ ε_{max}	Second-order decay k/ε (cm sec^{-1})
Benzene	420	15,100	1·59	←absent→		
*Cyclo*hexane	415	10,200	5·85	330	2,900	$2·5 \times 10^6$
Ether	←absent→			325	13,600	Not measured
Tetrahydrofuran	←absent→			330	11,050	$4·5 \times 10^6$
Methanol (ref. 2)	←absent→			330	20,200	$1·05 \times 10^6$

electrons to form the anion, N^-, and hydrogen atoms to form the $\dot{N}$H radical. Each of these species has a distinct absorption spectrum by which its presence can be detected. N^- was not observed in any of the five solvents listed in Table 1; instead, either N^T or $\dot{N}$H or a mixture of the two was usually detected. The spectrum of N in *cyclo*hexane is shown in Fig. 1. It has two peaks at 390 and 415 mμ which are almost identical with those previously observed for N^T (ref. 2) and an absorption band at 330 mμ assigned to N.H (ref. 3). In confirmation of these assignments it was found that the decay of the N^T band is always first order and that of the $\dot{N}$H band is second order. The relevant results are given in Table 1.

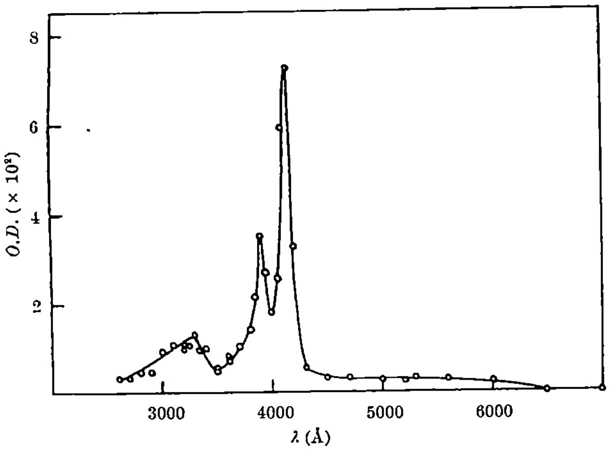

Fig. 1. Absorption spectrum of 9·8 mM naphthalene in *cyclo*hexane taken at the end of a 2-μsec pulse of 4-MeV electrons

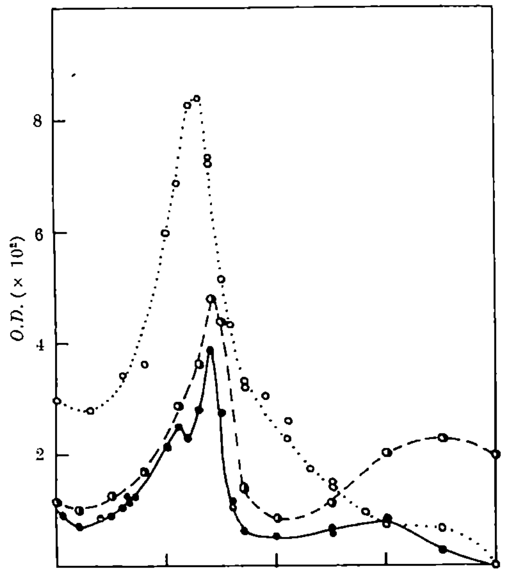

Fig. 2. Absorption spectra of solutions of benzophenone in benzene (···O···), *cyclo*hexane (—●—) and tetrahydrofuran (--◐--) taken at the end of a pulse of 4 MeV electrons

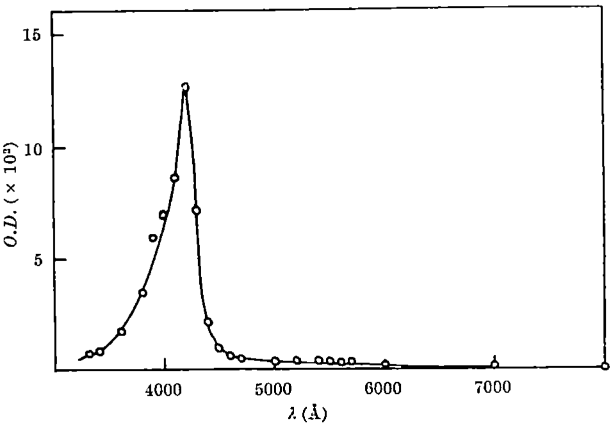

Fig. 3. Absorption spectrum of pulsed benzene solution containing 15 mM benzophenone and 9·7 mM naphthalene

The triplet state of the solute may be formed either by a spin-permitted energy transfer from a high-energy triplet state of the solvent, S, (equation (1)) or by electron exchange (equation (2)) with a secondary electron or

$$S^T + N \rightarrow S + N^T \qquad (1)$$

$$e^-(\uparrow) + N(\uparrow\downarrow) \rightarrow N^T(\uparrow\uparrow) + e^-(\downarrow) \qquad (2)$$

possibly as the result of a collision of N^- with a positive ion. The first of these is obviously appropriate to benzene as a solvent but cannot be true for *cyclo*hexane unless a higher excited state of this solvent decomposes forming a molecule in a suitable triplet state, for example, as in equation (3):

$$C_6H_{12} \rightsquigarrow C_6H_{12}^*;\ C_6H_{12}^* \rightarrow H_2 + C_6H_{10}^T;$$
$$C_6H_{10}^T + N \rightarrow C_6H_{10} + N^T \qquad (3)$$

The last mechanism is unlikely to be important in non-polar media such as C_6H_6 and C_6H_{12}.

The NH radical may arise from (*a*) electron capture by N followed by proton transfer from a protic solvent molecule or a molecular ion to N^- (equation (4)) or (*b*) hydrogen atom scavenging by the solute (equation ((5))

$$e^- + N \rightarrow \dot{N}^-;\ N^- + RH \text{ or } RH^+ \rightarrow \dot{N}H + R^- \text{ or } R \qquad (4)$$

$$H\cdot + N \rightarrow \dot{N}H \qquad (5)$$

or (*c*) hydrogen atom abstraction from the solvent by the triplet state (equation (6)):

$$N^T + RH \rightarrow \dot{N}H + R\cdot \qquad (6)$$

Mechanism (*a*) will only be possible in polar media where charge separation can occur and is the probable mechanism in methanol (protic solvent in which the electron can be solvated) and tetrahydrofuran (aprotic but may well solvate the electron). Mechanism (*b*) is likely in *cyclo*hexane, where scavengeable hydrogen atoms are known to form part of the primary radiolysis products, but may be less likely in benzene which shows marked auto-scavenging power[4]. Mechanism (*c*) is possible for *cyclo*hexane but is known to be impossible for benzene[2a]. The pattern discernible in Table 1 is thus broadly that expected, but we cannot be sure whether mechanism (*b*) or

(c) is predominant in the case of *cyclo*hexane. Since the NH band did not perceptibly increase as the N^T band decayed in this solvent we think that (b) is the more likely origin of NH in this liquid.

(2) *Solutions of benzophenone* (BP). Fig. 2 shows the spectra obtained in benzene, *cyclo*hexane and tetrahydrofuran, and Table 2 summarizes the data. The spectra of the ketyl, $\dot{B}PH = \varphi_2\dot{C}OH$, and its anion, $BP^- = \varphi_2\dot{C}O^-$, have been shown to have $\lambda_{max} = 540$ and 610 mμ in water–isopropanol mixtures[2a], and $\varepsilon^{545 m\mu}$ for $\dot{B}HP$ is $5{\cdot}1 \times 10^3$ M^{-1} cm^{-1} (ref. 6), and since the spectral characteristics of BP^T are also well known and this decays by a first-order law, whereas $\dot{B}PH$ decays bimolecularly, the assignments in Table 2 can be made with some confidence. The pattern is evidently similar to that for naphthalene solutions in that BP^T is formed in a non-polar solvent, but since benzene is an auto-scavenging solvent for H atoms and cannot transfer a hydrogen atom to BP^T no $\dot{B}PH$ is formed. BP^T is not observed in *cyclo*hexane in accordance with expectation because it readily abstracts a hydrogen atom from this solvent. A slight difference exists in that BP^- is formed but not N^- in tetrahydrofuran.

Table 2. TRANSIENT SPECIES IN THE PULSE RADIOLYSIS OF BENZOPHENONE SOLUTIONS

Solute concentration (mM)	Species Solvent	BP^T			$\dot{B}PH$			BP^-
		λ_{max} (mμ)	G ε_{max}	$t_{1/2}$ (μsec)	λ_{max} (mμ)	G ε_{max}	k/ε (cm sec^{-1})	λ_{max} = 700
12·1	Benzene	530	11,700	2·11 (ref. 4)	←Probably absent→ or small amounts			Absent
7·9	*Cyclo*-hexane	←Absent or only minor→			540	6,300	$1{\cdot}74 \times 10^6$	Possibly trace*
13·8	Tetrahydrofuran	←Absent or only minor→			545	6,200	$1{\cdot}76 \times 10^6$	Present

Porter and colleagues[2,6] have shown that energy transfer from BP^T to N (equation (7)) occurs readily and when a benzene solution containing 15·5 mM BP and 9·7 mM N was irradiated only the N^T spectrum was observed (Fig. 3).

$$BP^T + N \rightarrow BP + N^T \qquad (7)$$

It is interesting that $G\ \varepsilon^{420}$ is in this case 17,850, whereas its value in the absence of BP but at the same naphthalene concentration was 15,100 (Table 1), which has implications for the mechanism of formation of triplet states of solutes which we propose to investigate.

(3) *Solutions of diphenyl* (φ_2). Only a limited number of experiments were made with this solute but they sufficed to indicate: (i) that no φ_2^- is formed in 8·1 mM solution in 3-methylpentane, although Hamill *et al.*[7] find that this is produced by γ-irradiation of this solution in the glassy state at 77° K; (ii) in 3-methyl pentane only a single sharp peak is formed at $\lambda_{max} = 360$ mμ, $G\ \varepsilon^{360} = 16{,}600$, which decays unimolecularly with $t_{1/2} = 3{\cdot}4$ μsec, and this we assign to the triplet $\varphi_2{}^T$ (this assignment is in accord with that of Porter and Windsor[8] from investigations of the flash photolysis of φ_2 in liquid paraffin); (iii) pulsed 10·7 mM φ_2 in tetrahydrofuran gives a more complex spectrum with three peaks, one at 360 mμ (which we tentatively assign to $\varphi_2{}^T$), one at 305 mμ, which might be φ_2H, and one at ~400 mμ which might be part of the φ^{2-} band system.

We thank the Department of Scientific and Industrial Research for financial help and for the award of a research fellowship to one of us (T. J. K.), and Dr. Davies, Dr. Ebert and Mr. Foxall, of the Christie Hospital and Holt Radium Institute, for help with these experiments. These experiments were carried out in the laboratories of Associated Electrical Industries, Ltd.

---

* Dr. E. J. Land informs us he has definitely observed BP- in this system.

INTERFEROMETRIC RAMAN SPECTROSCOPY USING INFRA-RED EXCITATION

By DR. G. W. CHANTRY and DR. H. A. GEBBIE

Basic Physics Division, National Physical Laboratory, Teddington, Middlesex

AND

DR. C. HILSUM

Royal Radar Establishment, Malvern

WE are reporting here the first results of the researches in the Basic Physics Division of the National Physical Laboratory, aimed at extending the usefulness of Raman spectroscopy by developing methods of infra-red excitation. Many pure substances and industrial intermediates are strongly coloured and their Raman spectra cannot be recorded using ultra-violet and visible lines, but nearly all compounds have a region of transparency in the near infra-red. If, therefore, methods could be developed in which a selection of infra-red exciting lines were used, Raman spectroscopy could be more widely applied and could become a valuable complement to standard infra-red analysis.

The basic difficulty comes from the fact that as the wavelength of the exciting line is increased, the scattered intensity falls off rapidly. It is therefore important to seek a spectroscopic technique which makes best use of the reduced amount of scattered radiation, and in this respect the virtues of the Michelson interferometer plus Fourier transform method are now well known. An interferometer for the near infra-red region which uses a strip-hinge mirror movement has already been described[1]. The large intensity ratio between direct and Raman scattered radiation poses technical problems of maintaining linearity in the amplifying and detecting systems. It is therefore an important consideration in choosing the source that there should be means of discriminating one from the other. In this respect the gallium arsenide injection laser has the great advantage that in any experiment requiring the elimination of the exciting line from the scattered radiation, a gallium arsenide filter may be placed in front of the photomultiplier. Gallium arsenide has a very steep absorption edge the wave-length of which can be changed by varying the temperature. Thus the filter can be set to attenuate strongly the exciting line and transmit any Raman lines of longer wave-length

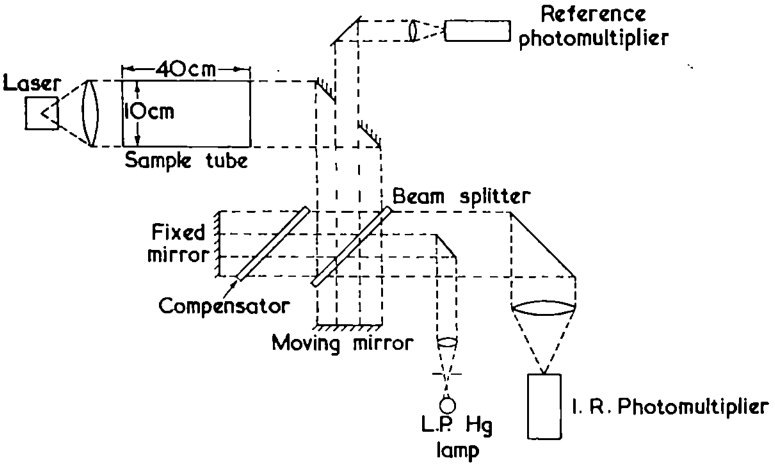

Fig. 1. Experimental arrangements for near infra-red Raman spectroscopy

that may be present. Though the use of such a filter prevents the observation of the anti-Stokes lines and has not been used in these first observations reported here, we believe that in less-favourable cases where absorption in the sample itself does not provide the discrimination, this property of gallium arsenide will be of value.

Our sample tube used with the laser differs from conventional Raman sources in having plain glass windows at each end so that the exciting radiation passes through the sample and directly into the interferometer. The laser is pulsed and the photomultiplier voltage pulses are 'gated' to remove the noise between pulses. The output is recorded digitally at intervals of mirror movement equal to the wave-length of the mercury violet line *Hg* 4047 Å and spectra are obtained by Fourier transformation in a digital computer. The experimental arrangement is shown in Fig. 1.

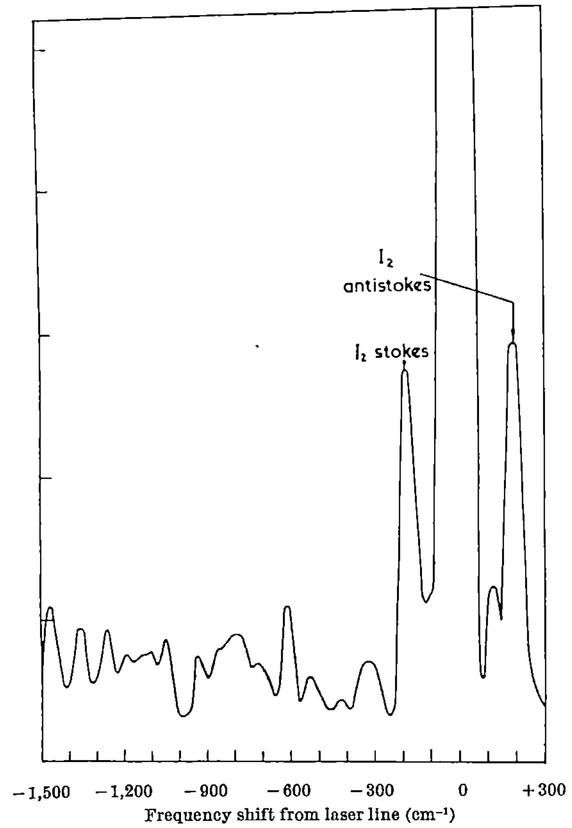

Fig. 2. Raman spectrum of iodine dissolved in carbon tetrachloride

Using this apparatus we have observed the Raman spectrum of iodine dissolved in carbon tetrachloride at a molar ratio of 1 : 1,000. The spectrum is shown in Fig. 2. The Stokes and anti-Stokes lines of iodine show up clearly at ± 200 cm^{-1} with an intensity of about 1 per cent of the laser-line intensity. Such a high value, together with the approximate equality of the Stokes and anti-Stokes intensities, indicates that the emission is stimulated. Further evidence has been obtained by sending the beam into the cell at an angle and showing that the ratio of Raman intensity to laser intensity remains unchanged. This proves that the Raman emission is angularly correlated with the laser beam—as expected for stimulated emission. The spectrum obtained with skew illumination also shows the Raman line ν_1, of carbon tetrachloride at 460 cm^{-1}.

We have also observed strong Raman emission from very dilute (M/800) solutions of the cyanine dye 1,1′-diethyl thia-tricarbocyanine iodide in methanol and the spectrum is shown in Fig. 3. The absorption spectrum of this dye shows an intense ($f \approx 1\cdot0$) band peaked at 13,200 cm^{-1}. The structure of this absorption suggests that the compound will show a strong Raman spectrum and consequently a stimulated Raman effect is to be expected. The Raman features are probably unresolved multiplets and their intensity is such (10 per cent for the 300 cm^{-1} line) as to suggest that these may in fact be stimulated. The anti-Stokes lines are not observed because of strong absorption by the liquid.

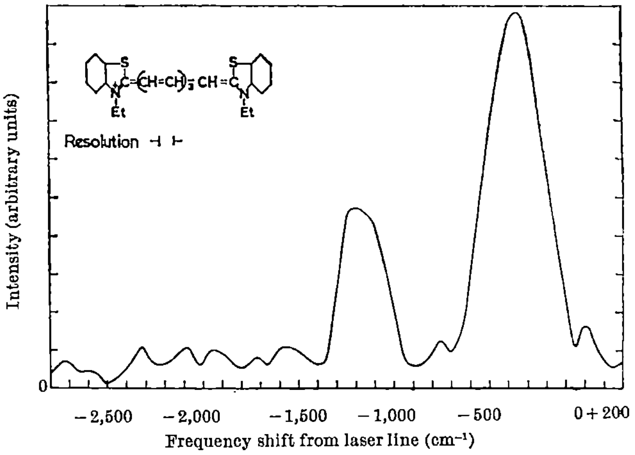

Fig. 3. Raman spectrum of 1,1′-diethyl thia-tricarbocyanine iodide dissolved in methanol

The possibilities of Raman measurements with near infra-red exciting lines have thus been demonstrated. We believe, therefore, that technical Raman spectroscopy with a wide field of application could be achieved with a combination of interferometer and stimulated emission sources. Such sources will be available in an increasing range of wave-length and power as time goes on, and should permit most substances to be investigated by choosing the source wave-length to lie in a region of low absorption.

We thank M. J. Coupland, Services Electronics Research Laboratory, for supplying the laser.

This work forms part of the research programme of the Basic Physics Division of the National Physical Laboratory and is published by permission of the Director.

SCHEELITE STRUCTURES: SINGLE CRYSTAL GROWTH AND TRANSMISSION DATA

By Dr. B. COCKAYNE and J. D. RIDLEY

Ministry of Aviation, Royal Radar Establishment, Great Malvern

SEVERAL of the scheelite structures are now of interest as possible host lattices for laser materials. It is already reported in the literature[1-3] that many of these structures have been grown from the melt in single crystal form using the Czochralski technique[4] but, with the exception of $CaWO_4$ (refs. 5 and 6), little information has been published on the transmission properties of this group of materials. The results are now reported for the single crystal scheelites $SrWO_4$, $BaWO_4$, $CaMoO_4$ and $SrMoO_4$, and are compared with similar data for $CaWO_4$. Some aspects of the growth process are also described.

The technique of crystal growth for all the crystals was identical to that described fully elsewhere for $CaWO_4$ (ref. 6), in which the starting material, prepared as a powder by Levy-West Laboratories Ltd., is melted in an iridium crucible using radio-frequency induction heating. The crystals were pulled from the melt in an argon/oxygen atmosphere. For $SrWO_4$ and $BaWO_4$, only 4 vol. per cent of oxygen was required in the atmosphere above the melt surface to prevent reduction of the material, which imparts a dark-brown colour to the crystal; these conditions are this identical to those reported for $CaWO_4$ (ref. 6). A similar volume of oxygen in the atmosphere was, however, insufficient to suppress the reduction of $CaMoO_4$ and $SrMoO_4$ crystals, which exhibit a blue colour characteristic of the lower oxides of molybdenum. The reduction can be suppressed to a certain extent by increasing the oxygen content of the atmosphere to 10 vol. per cent but is not entirely removed by this proportion. Single crystals of $BaMoO_4$ were also grown, but these cleaved catastrophically on cooling and contained a precipitate which rendered the material opaque, thus suggesting that the starting material was impure.

During the course of the work the melting-points of this group of materials were measured and are given in

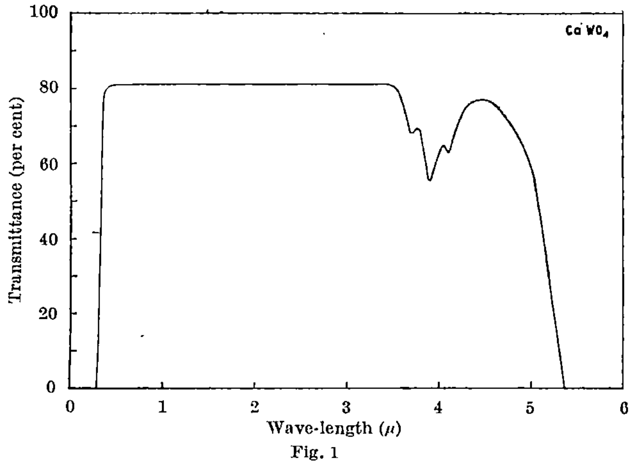

Fig. 1

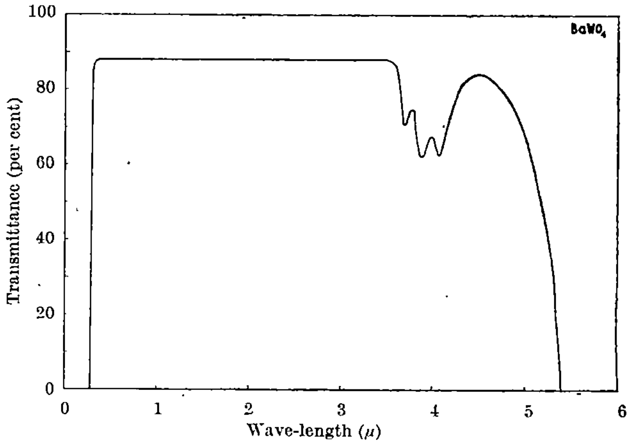

Fig. 3

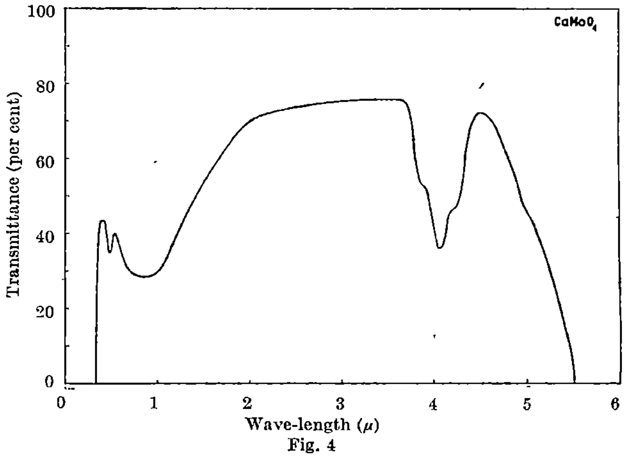

Fig. 4

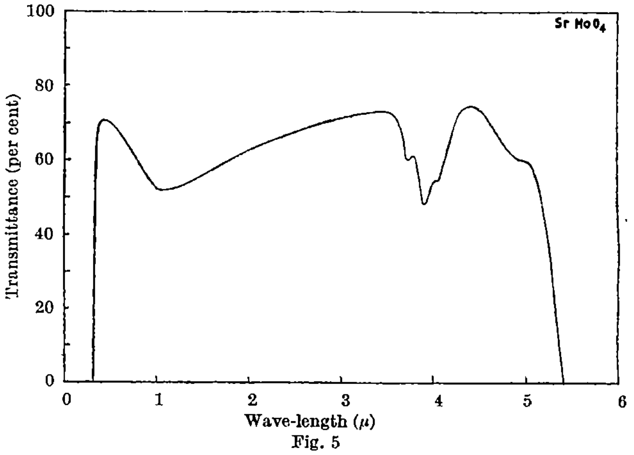

Fig. 5

Table 1

Scheelite compound	Melting point (°C)
$CaWO_4$	1,566
$SrWO_4$	1,566
$BaWO_4$	1,485
$CaMoO_4$	1,449
$SrMoO_4$	1,468
$BaMoO_4$	1,459

Table 1. These were determined using a thermal arrest method and by measuring the temperature at which an 'island' of solid, lifted just above the melt on a thermocouple, was observed to melt and fall back into the crucible. The latter method was found to be the most reproducible and gave results repeatable to ± 3° C.

The specimens for transmission studies were prepared as 5-mm thick sections by cutting the crystals with a wire saw and subsequent polishing with successively finer grades of diamond paste. The variation of transmittance with wave-length for the scheelites examined is shown in Figs. 1–5; the measurements were made at room temperature using standard Perkin–Elmer spectrophotometers. The transmission properties of these materials are very similar apart from the absorption in the molybdates at wave-lengths up to 2μ, which is most probably due to the particles imparting the blue colour to the crystals.

A RECENT VOLCANIC ERUPTION ON BOUVETOYA, SOUTH ATLANTIC OCEAN

By P. E. BAKER and J. F. TOMBLIN

Department of Geology and Mineralogy, University Museum, Oxford

THE Norwegian island of Bouvetøya (54° 26′ S., 3° 24′ E.) is the southernmost of the volcanic islands rising from the Mid-Atlantic Ridge. About 9·5 km from east to west and 7 km from north to south, it reaches a height of 935 m above sea-level. The gently domed upper part of the island ends abruptly in rock cliffs up to 335 m high along the western side, but to the east it is bounded by lower ice cliffs. Except for the steep sea cliffs the entire island is covered by ice which has a maximum thickness on the coast of about 60 m.

An account of the physiography and structure of Bouvetøya by Holtedahl[1] was based largely on information and photographs supplied by the *Norvegia* expeditions 1927–28 and 1928–29. Rock specimens collected during these expeditions were later described by Broch[2], who also presented five chemical analyses.

On January 1, 1958, during an aerial reconnaissance made at the request of Rear-Admiral H. H. Biermann, observers from U.S.C.G.C. *Westwind* obtained photographs of Bouvetøya showing a low platform at the foot of the

cliffs on the north-western side of the island, 1 km to the south of Kapp Circoncision. Lieut.-Commander A. B. Crawford, who afterwards examined the photographs, concluded that the platform did not exist in February 1955 when he landed on Kapp Circoncision with a party from S.A.S. *Transvaal*. This was finally confirmed on December 10, 1959, when Lieut.-Commander Crawford, aboard M.V. *Polarbjørn*, observed the new feature for the first time. On March 31 and again on April 2, 1964, British Antarctic Survey scientists were landed by helicopter from H.M.S. *Protector* to investigate the new platform. On the second occasion they were accompanied by scientists from the South African Research Ship *R.S.A.*

Extending for about 650 m from north to south and for 365 m at its widest point from east to west, the new platform has a hummocky surface rising to an average height of 25 m and a maximum of 40 m above sea-level. To the east it is flanked by talus fans derived from the cliffs behind, to the west it terminates in low sea cliffs, and to both north and south it is adjoined by broad beaches. The feature is evidently the result of a volcanic eruption which involved the extrusion of a small volume of new lava and the uplift of a considerably larger volume of older lavas and pyroclastics: the magma was apparently highly viscous at the time of eruption. No crater is visible and there are no distinct lava flows. The central part of the platform consists of irregular patches of a new block lava resting on disturbed older material; the new lava appears to be concentrated on the higher ground towards the north-east, but it also forms well-developed tumuli about 12 m in diameter and 5 m high a short distance to the south-west of the highest point. Flaggy slabs of lava, often showing flow-banding, are breaking away from the tumuli along prominent concentric joint surfaces. The northern and southern parts of the new platform appear to be composed entirely of upheaved debris including boulders and fragments of old lava and hillocks of a greenish tuff and ash, similar to that which crops out in the cliffs behind.

Individual blocks of the new lava have reddish-brown surfaces but are greenish-grey in the interior. Pyroxene phenocrysts are conspicuous in the hand specimen. In thin section, phenocrysts of plagioclase, zoned chiefly within the andesine range, clinopyroxene, ore and occasionally olivine are seen in a fine-grained matrix of plagioclase, alkali feldspar, pyroxene and ore. Both apatite and calcite are abundant accessory constituents. The mineralogy of the new lava suggests a trachyandesite composition.

This small eruption on Bouvetøya, which evidently occurred between February 1, 1955, and January 1, 1958, is another instance of volcanic activity along the Mid-Atlantic Ridge within the past decade, other eruptions having occurred in the Azores (1957), Tristan da Cunha (1961) and Iceland (1961 and 1963).

We thank the Norwegian Government for permission to land on Bouvetøya; also the captain, officers and ship's company of H.M.S. *Protector* for their assistance, and Lieut.-Commander A. B. Crawford for supplying details of the discovery of the new platform. The investigation was carried out as part of a British Antarctic Survey project and during the tenure of Department of Scientific and Industrial Research/NATO awards.

LETTERS TO THE EDITOR

PHYSICS

Distribution of Particle Size in Dust

DAVIES[1] says that when the power law is used in the form:

$$dN/dD = KD^{-\gamma} \qquad (1)$$

where N is the number of particles below diameter D, then K is not just an arbitrary concentration factor. He then states that the smallest particle size (D_S) is a function of K, a statement that appears to me to be just the opposite of the real situation.

In practice both D_S and D_L are fixed by factors such as the resolution limit of the microscope being used and the largest particle that the sampling instrument can sample, and K will be a function of both these quantities. Solving for K in equation (3) of Davies's communication we get:

$$K = N_T(\gamma - 1)/[D_S{}^{1-\gamma} - D_L{}^{1-\gamma}] \qquad (2)$$

From equation (2) it is apparent that K is proportional to N_T, but as it also depends on γ and D_S it is not, as Davies pointed out, merely a concentration factor. The dependence of K on γ and D_S is due to the fact that we are dealing with a probability density function and not an ordinary regression situation.

The appropriate probability density function is:

$$P(D) = (\gamma - 1)D^{-\gamma}/(D^{1-\gamma} - D_L{}^{1-\gamma}) \qquad (3)$$
$$\text{for } D_S \leqslant D \leqslant D_L$$

and the cumulative probability for particles of diameter less than D is:

$$(D_S{}^{1-\gamma} - D^{1-\gamma})/(D_S{}^{1-\gamma} - D_L{}^{1-\gamma}) \qquad (4)$$

and hence:

$$P(D) = \frac{dP(D)}{dD} = (\gamma - 1)D^{-\gamma}/(D_S{}^{1-\gamma} - D_L{}^{1-\gamma}) \qquad (5)$$

$$\text{and} \quad \frac{dN}{dD} = N_T \frac{dP(D)}{dD} = KD^{-\gamma} \quad \text{(as it should)} \qquad (6)$$

If $dP(D)/dD$ is plotted against D on log–log paper the result will be a straight line; however, I do not see why $P(D)$ (or N per cent) when plotted against D on log-probability paper can be expected to yield a straight line as we are not dealing with the log normal distribution.

If D_L is much larger than D_S ($D_L = 100\mu$ is large), then:

$$1 - P(D) = (D^{1-\gamma} - D_L{}^{1-\gamma}) / (D_S{}^{1-\gamma} - D_L{}^{1-\gamma})$$
$$\approx (D/D_S)^{1-\gamma} \qquad (7)$$

and plotting results of equation (7) on log–log paper gives a linear relationship of slope ($1-\gamma$). In practice one plots $1 - N/N_T$ against D and obtains γ from the slope of the line.

A final comment is that when drawing graphs of any distribution it is often very misleading to omit parts of the graph and, if possible, this should be avoided (for example, in Fig. 1 of Davies's paper for $K = 10$, $D_S = 0{\cdot}1\mu$, and hence the curve for the interval $D_S \leqslant D \leqslant 1\mu$ has been omitted although a number of particles would occur in this range).

[1] Davies, C. N., *Nature*, **201**, 172 (1964).

DR. DAVIES[1] refers to the significance of the multiplier K in the 'power law' frequency function $dN = KD^{-\gamma}\,dD$ describing the size distribution of particles. His remarks, however, could apply to any function of the general form $Kf(D)$. The multiplier K does not in any way define the relative frequencies with variation of D; this is completely defined by $f(D)$. If, however, two or more distributions were combined, it would be necessary to specify individual values of K in order to define the contributions of the different components:

$$K_1f_1(D) + K_2f_2(D), \text{ etc.}$$

Apart from its use with a multi-term distribution the multiplier K could be used to adjust the value of a definite integral to a specific total, although it is rarely used for this purpose. In the examples shown by Davies the total is fixed at 100 per cent and the lower limit of the integral is indirectly varied by varying K. His curves express the cumulative per cent below size where 100 per cent corresponds to:

$$K\int_{D_S}^{D_L} D^{-\gamma}\,dD$$

The four curves correspond to different values of K but have the same upper size limit of $D_L = 100\mu$. The lower size limit D_S is not directly specified, but since the total of the integral is fixed at 100 it follows that D_S is completely determined by the value of K. The curves, therefore, demonstrate only the change of visual shape (that is, not mathematical shape) that must result from plotting any given function over a progressively wider range of D while maintaining the total unchanged.

Thus, although the distribution is completely specified by $D^{-\gamma}$, the visual shape of the curves calculated from it can be varied according to the way the results are calculated and displayed.

Light from Shocked and Detonating Powders

Blackburn and Seely[1] have published evidence that the light from strongly shocked granular salt was largely independent of the interstitial gas. They inferred that it did not (as I had thought[2,3]) arise from compression of the gas, and assumed that the same conclusion would apply to detonating explosive powders. While this extrapolation is plausible, it would be advantageous to have it confirmed.

In a recent communication[4], however, Blackburn and Seely refer to a side-on still photograph taken by Cumming in this laboratory[5], which shows a marked dependence on the included gas (butane, air, argon) for PETN detonating in a water-sheathed plastic tube. Against this, they present an end-on time-resolved record, in which the first flash of light from the free surface of PETN is equally intense in butane, methane and air. As they remark, it is difficult to reconcile these results.

The discrepancy is not due to the fact that Cumming's published photograph was a still one. This photograph was one of a set of five, the other four time-resolved and all showing the same effect. We have recently taken side-on streak records of a further five PETN detonations in polyvinyl chloride, cellulose acetate and 'Perspex' tubes, with and without water sheaths. These records show in general an unmistakable difference between butane, air and argon: Fig. 1 is an example. It is true that our time-resolution is moderate (1 mm/μsec) and primary light from the detonation front may therefore conceivably be masked by later light which would be separated under high resolution. However, even if this is so, it does not alter the fact that the total light output depends very much on the nature of the gas.

To assess the effect of the confining tubes, and for comparison with Blackburn and Seely's end-on free-surface photographs, we have taken numerous streak records of PETN lying in the lower part of a sealed 'Perspex' trough, divided into three compartments in tandem, through which butane, air and argon were circulated. The camera viewed the PETN surface from above. The contrast between light intensities in the three gases is so great as to present a problem in printing from the negative. In Fig. 2 the print exposure has been lengthened to accentuate the air line. The argon line is still submerged in a cloud of intense scattered and secondary light, while the butane line has already almost disappeared, although quite distinct on the negative. Longer print exposure suppresses the air line also and isolates the argon line.

We have repeated Blackburn and Seely's end-on experiment, using butane and air only. Although the record shows a more intense primary line from the air, the difference is much less pronounced than in Fig. 1. Even a single free-surface test of this kind can be regarded as significant, since the absence of atmospheric shock light from the butane proves that the gas was successfully circulated, which is not so easy to guarantee with confined charges.

It is generally thought that the lateral surface layer of a detonating explosive column may react less quickly and completely than elsewhere. When poorly confined, the surface layer may even survive unreacted. It can therefore be suggested that what we record in a side-on shot is a rather muted version of affairs inside the mass of explosive. If end-on shots report more extreme conditions, the similar behaviour of air and butane in such shots may be due to the greater shock intensity. One would then expect the differences to reappear with a milder explosive. We have carried out a few experiments similar to Blackburn and Seely's with nitroguanidine at loading densities of 0·2, 0·185 and 0·17 g/cm^3. The charges were 1 in. in diameter, 3 in. long, and simultaneous records showed steady speeds between 2 and 3 km/s, according to density. At 0·20 g/cm^3, there was rather little difference between air and butane, though the air was somewhat brighter.

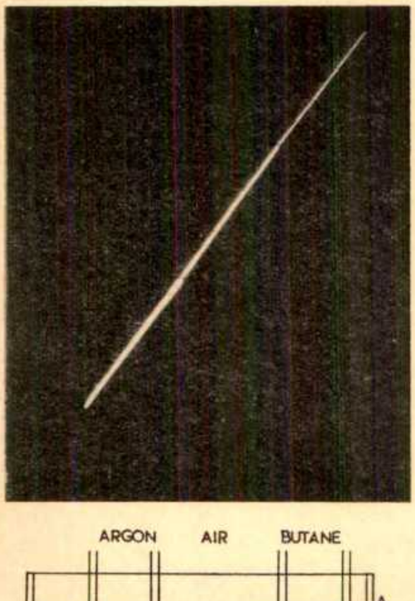

Fig. 1. Streak photograph of PETN detonating in a 0·5 in. internal diam., 0·625 in. outer diam. polyvinyl chloride tube within a tank of water. Butane and argon were passed continuously through the first and third sections, while the second contained air. *A*, initiator

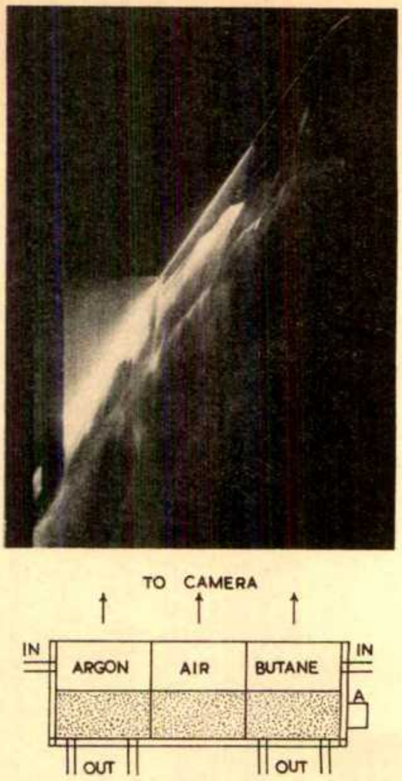

Fig. 2. Streak photograph of PETN detonating in a partially filled trough. The camera slit image lay along the median line of the powder surface. *A*, initiator

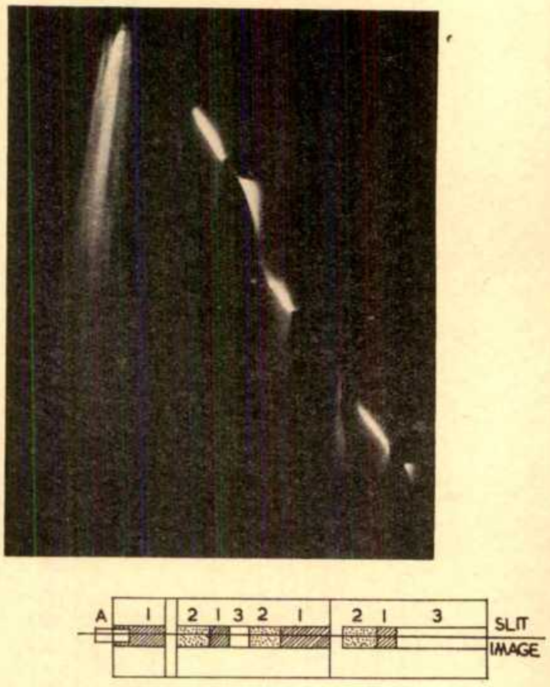

Fig. 3. Streak photograph of detonations and shocks at 1 atm. and 200 atm. initial pressure. 1, Plastic explosive; 2, PETN; 3, sodium chloride, in 0·375 in. diam. axial holes in square-sectioned 'Perspex' blocks. *A*, initiator

As density decreased, both primary lines became less bright, and the contrast between them increased. At 0·17 g/cm^3, the air line was still distinct; but the butane line had almost disappeared. One should not attach great weight at the moment to this slender evidence; but it is at least consistent with the foregoing ideas, which may also be relevant in comparing explosive and inert powders.

An important part of the earlier evidence collected by Blackburn and Seely was the persistence of light in a shocked inert powder which had been highly evacuated. We have tried to supplement this by experiments on both inert and explosive powders in which the initial pressure was raised to 100 or 200 atm. The argument here is that one would expect the shock pressure ratio and thus the gas pocket temperatures to be much reduced[3]. Fig. 3 shows the experimental arrangement and a typical trace. The first plastic charge transmitted detonation through the 'Perspex' barrier to the first PETN primer in the 1-atm. section, which initiated the second plastic charge, and this delivered a standard blow to the sodium chloride. The transmitted shock set off the second PETN primer and then the third plastic charge, so that the process was repeated symmetrically in the high-pressure section. It seems therefore permissible to compare the behaviour of the first PETN and the sodium chloride charges at 1-atm. and at high initial pressure.

One can see a definite reduction in light output from the PETN at 200 atm., and more conspicuously from the salt, in which the trace dies out very quickly. Similar, but rather less marked, effects were found at 100 atm. However, it is perhaps more significant that so much light persists at all at these high initial pressures.

I thank Dr. Seely for sending me advance details of his experiments, and for his comments. I thank also Mr. Cumming for his advice, and Mr. H. Andrew and Mr. J. Logan for assistance in the experiments.

Resistance Inequalities

IT is well known that the electrical resistance tensor r is symmetric in the absence of a magnetic field. It is the purpose of this communication to point out that this implies that certain inequalities exist between the diagonal and off-diagonal elements of r. To obtain these we note that since r is symmetric it can always be diagonalized by a rotation of co-ordinate axes, and the resulting diagonal tensor will have all its diagonal elements positive, since these will be the resistances along the 'new' axes. Hence r, considered as a matrix, is positive-definite and this implies that inequalities between its elements must exist of the form:

$$r_{xx}r_{yy} \geqslant r^2_{xy}$$

GEOLOGY

The British Mesozoic Committee

LAST year, a note was published in *Nature*[1] which summarized the recommendations of an international colloquium at Luxemburg on the definition of Jurassic stages and added the views of the British Mesozoic Committee on these recommendations. The stated object of this note was to give other British Mesozoic specialists the opportunity of considering the recommendations and of expressing their opinions about them. As a result of this and of further recommendations from other national committees brought forward at a meeting of the international Mediterranean Mesozoic Committee in September 1963, the British Committee decided that further discussions were necessary. A general meeting was, therefore, arranged at the Geological Society of London on February 26. This meeting, which was attended by 65 geologists who were specializing in the Mesozoic, was intended to guide the Committee in framing its further recommendations to the international organization.

Immediately after the general meeting, the Committee agreed on the following recommendations: (1) The British Mesozoic Committee considers that, not withstanding the Statement of Principles embodied in Part 25 of the twenty-first Session of the International Geological Congress, Mesozoic stages must in practice be defined in terms of faunal zones (that is, "belts of strata, each of which is characterized by an assemblage of organic remains, of which one abundant and characteristic form is chosen as index" Marr 1898, Arkell 1933). (2) As a general principle, only the base of each stage should be regarded as fixed, preferably by reference to a specified point in a type section for the lowest zone. (3) The Rhaetian should be regarded as the topmost stage of the Triassic System, and no part of it should be included in the Jurassic. (4) The terms Lias, Dogger and Malm should be rejected as international stratigraphical units. (5) The Jurassic should be divided into Lower, Middle and Upper divisions. (6) The British Committee does not recommend the definition of named substages. (7) The British Committee does not consider that a case has been made for the recognition of the Aalenian as a separate stage. (8) The Bajocian Stage and the Middle Jurassic should be regarded as beginning with the *opalinum* Zone. (9) There exists a difference of opinion among British specialists, but a majority favour the inclusion of the Callovian Stage in the Upper Jurassic. (10) In the interests of achieving international stability and uniformity of nomenclature, British specialists have no objection to the eventual dropping of the term 'Portlandian' as an international stage name. (11) Many British specialists favour the retention of the Kimmeridgian Stage in its broader sense, up to and including the *pallasioides* Zone. However, the British Committee recommends that only the base of this stage should be defined (as the *baylei* Zone) and are prepared to accept the next successive stage as the Volgian, as at present defined by the Jurassic Commission of the Stratigraphical Committee of the U.S.S.R. (12) The British Committee prefers the retention of both the Volgian and Tithonian Stages at the top of the Jurassic, and both the Ryazanian and Berriasian Stages at the bottom of the Cretaceous until such time as the Boreal and Tethyan provinces have been adequately correlated.

Postscript. The above recommendations were presented at a meeting of the International Committee near Marseille in May. They were all accepted, except that a majority favoured the retention of the Aalenian as a stage and the placing of the Callovian in the Middle Jurassic (though the objections of the British and Russian committees to this were to be forwarded to the International Congress). Also the Volgian Stage was preferred as the top division of the Jurassic, with the Tithonic (*sic*) to be retained only as a facies name, since it contravenes the rules of stratigraphical nomenclature.

Marine Levels in South Italy

AFTER a personal discussion with Mr. A. E. Gunther, I am writing with his encouragement to comment on his communication in *Nature*[1] and with reference also to an earlier article in the *Illustrated London News*.

In those publications Mr. Gunther suggested that the supposed presence of *Lithodomus* borings in the columns of the temples at Paestum, and the presence of marine erosion terraces at a similar height of about 20 m in various parts of Italy and Sicily, combine to indicate an extensive rise and fall of relative sea-level in the whole of this area between about A.D. 500 and A.D. 1500.

I feel that it is necessary to comment on this hypothesis since the literature shows that geologists and archæologists tend to accept uncritically publications on this topic, where they would be far more cautious in the mainstream of their respective disciplines. In the past this has resulted in misleading papers having a long-standing effect on the literature.

This is not the place to produce a massive list of authorities, but I wish simply to outline a point of view which can be checked by reference to recent authors on Pleistocene sea-levels, and regional archæology.

First, there has been no eustatic change of sea-level greater than 2 m in the past 2,000 years, and probably none more than 1 m. During the past million years there have been frequent large oscillations of sea-level due to glacial control, resulting in the sea passing through the present level many times. There are thus many Pleistocene erosion traces within 20 m of present sea-level, but all older than 2,000 years.

Owing to the seismicity of the west Italian coast it is possible for local earth movements, such as those which have occurred in the north Bay of Naples, to lower and raise archæological remains in such a way that erosion marks on the buildings are aligned with nearby Pleistocene traces of much greater age.

Many of the terraces at or near 20 m in south Italy are of such a nature as to have required hundreds, if not thousands, of years of erosion, while a postulated 20 m sea-level between A.D. 500 and A.D. 1500 can only have remained at its maximum altitude for one century at the outside. If such a widespread submersion and uplift had occurred, 53 major coastal cities would have been inundated at a rate of 5–6 m per century, including Pisa, Civitavechia, much of Rome, Naples, Messina and Syracuse, as well as about 2,300 km² of land. Apart from minor references to the spread of malarial swamps, which can result from silting with no change of level, there is no literary evidence to support such an event, nor does archæological evidence support it.

Most of the sites in the area have been thoroughly excavated and there are no signs of general submersion, apart from a few scattered sites partly submerged to-day as a result of local earth movements. At Civitavechia, Rome, Naples, Salerno and Syracuse, there were buildings erected during the medieval period at water-level or within a few metres of it, and there is no evidence that marine sediments overlie these sites. Furthermore, the rapid accumulation of sediments at the mouths of many small rivers on the west coast of Italy implies a more or less constant relative sea-level, while if there had been a change much of this sediment would have been deposited farther inland and over archæological remains.

---

[1] Gunther, A. E., *Nature*, **201**, 909 (1964).

A. E. GUNTHER describes relatively large movements of uplift and subsidence of the land with respect to the sea in historical times in southern Italy. The *Lithodomus* borings at Paestum indicate a relative subsidence of the land, followed by an uplift of 18·5 m, in the time that has elapsed since the construction of the temples. If Gunther's contention that the uplift has occurred since the Middle Ages is correct, then an average rate of uplift of approximately 3–4 cm per annum is implied. In Calabria, however, where a number of colleagues and I have recently completed a geological survey of the whole province, at a scale of 1 : 25,000, for the Cassa per il Mezzogiorno, uplift has occurred at an appreciably slower rate.

A magnificent series of erosional levels occur round the coasts of Calabria, the highest reaching a height of 1,000 m above present sea-level. There is good evidence that the uplift movements, which raised the erosional surfaces to their present position, began during the Calabrian Stage of the Pleistocene, and, therefore, there has been approximately 1,000 m of uplift during the Quaternary. Assuming a duration of 10^6 years for the Quaternary, the average rate of uplift during this time was approximately 1 mm per annum.

Variations in the rate of movement can be demonstrated by considering the ages of the various levels. The lowest, extending to a height of 120 m above sea-level, is of Tyrrhenian age, as shown by the *Strombus bubonius* fauna present in the vicinity of Reggio di Calabria. The next higher terrace has been attributed to the Sicilian, and the level above that, with a lower limit of about 300 m, is probably of Calabrian age. The higher terraces, with the probable exception of the highest, 1,000 m level, can also be attributed to the Calabrian. It appears, therefore, that more than half the Quaternary uplift occurred during the Calabrian Stage, and that in post-Calabrian times the movement slowed down. Assuming the duration of the Calabrian was $3{\cdot}5 \times 10^5$ years, then the average rate of uplift during that time was approximately 2 mm per annum. Again, assuming an age of 4×10^6 years for the Tyrrhenian terrace, the average rate of uplift since that time has been about 0·3 mm per annum.

The variations discussed here are all relatively long-term. Geological evidence for shorter-term variations is lacking. Coming to modern times, Omori[1] has estimated that the average rate of uplift for the Calabro–Sicilian area, for for the period 1900–08, was 2–4 mm per annum. This figure is of the same order as those deduced above from the total Quaternary, the Calabrian and the post-Tyrrhenian uplifts, and leads one to assume that the rate of uplift in Calabria has been fairly constant throughout the Quaternary up to the present day. This rate of movement is significantly less than that quoted above for Paestum. The probable reason for this difference is that Paestum is located in a particularly active geological zone.

During the survey of Calabria no evidence for a modern reversal of the uplift movement was observed. The Holocene sediments of the coastal plain, extending into the river valleys, indicate that there has been a relative subsidence of the land since the end of the last glaciation, but this was probably caused by the return of glacial melt water to the oceans. In all probability the uplift movement continued during the Holocene, but the rise in sea-level was greater than the uplift of the land and therefore a relative subsidence resulted. The most recent evidence, provided by remnants of modern raised beaches, indicates that uplift is again dominant.

Two conclusions can be drawn from the foregoing discussion. First, modern movements of uplift and subsidence in southern Italy have not been uniform over the whole region and therefore correlation of levels based on height above sea-level cannot be relied on except over relatively short distances. Secondly, the hypothesis of a widespread 18-m historical level cannot be sustained.

Stream Deposition in the Mediterranean Area in Historical Times

C. Vita-Finzi[1] has indicated that stream action during the Middle Ages caused rapid changes synchronously over large areas in the Mediterranean, producing in the valleys a flat-topped alluvial fill into which the present river channels were later cut. During field-work in western Turkey, I noticed similar deposits in most of the basins even as far north as Gordion (Polatli) on the Sakarya. Up to now these deposits have not been dated, but a detailed examination of the Küçük Menderes delta (near Ephesus) showed that accumulation of sediment in the delta mainly occurred during the Hellenistic period (about 300–100 B.C.)[2]. The sequence of events in the delta could be dated by historical evidence; for a detailed discussion the reader is referred to the original paper. After a decrease in accumulation during the Roman period, almost no changes occurred from about A.D. 800 up to about 1935, when a canal was cut which shortened the river considerably and caused some new accumulation near the canal mouth. There is, of course, always the possibility that some time during the Middle Ages accumulation increased again and was followed by a period of severe marine erosion that obliterated all trace of the medieval accumulation, but this possibility seems to be rather remote, considering the regularity of the beach ridges that form the present coast.

The findings at the Küçük Menderes delta suggest that the river carried much more sediment seaward during the Hellenistic period than before and after. To explain the increase in sediment load an increase in soil erosion is suggested, due to an increase in deforestation and cultivation on the hill slopes during Hellenistic times when Asia Minor became Hellenized. The decrease in delta growth and the incision of the streams can be due to an after-effect of soil erosion: when most of the soil has been removed, there is little left on the nearly bare slopes to be transported any more, while the process of soil formation is far too slow to supply as much sediment to the streams as was transported when the old soils were eroded. The result is a decrease in sediment transport by the streams which leads, presumably, to incision and lowering of the stream-bed.

A certain measure of synchronicity in soil erosion, as suggested by Vita-Finzi for the Middle Ages, should not be surprising, as soil erosion may have increased more or less simultaneously in many regions in the Mediterranean due to disorganization and neglect after the break-up of the Roman empire. On the other hand, severe soil erosion may have occurred much earlier than the Middle Ages especially in the eastern Mediterranean. At one locality at least accumulation did not occur mainly after the Roman period but before.

MINERALOGY

An Occurrence of Görgeyite in Greece

The new mineral, görgeyite, was described in 1953 by Mayrhofer[1] from salt beds at Ischl, in Upper Austria, as $K_25Ca(SO_4)_6.1–1\frac{1}{2}H_2O$. In the same year, Mokievsky[2] announced the discovery by Nefedov of a sulphate mineral of comparable composition in salt deposits of Lake Inder, Kazakhstan S.S.R., to which the name mikheevite was given. That the two were identical was suspected by Fleischer[3], and after Nefedov[4] published further data on mikheevite, Meixner[5] showed that this was indeed the case. The name görgeyite has priority. We wish to record a third occurrence of the mineral.

A bore-hole, Astakós No. 1, was drilled recently by BP Exploration Co. (Greece), Ltd., about 9 km north-north-east of the town of Astakós in western Greece (approximate co-ordinates of the site: 38° 36′ 30″ N., 21° 07′ 35″ E.; elevation, 250 m). It encountered a thick sequence of Triassic evaporites, in which halite and anhydrite are dominant minerals, with polyhalite and dolomite present in smaller amounts. A sample of drill-cuttings from 1,544 m depth yielded a few anhedra, 2–4 mm in diameter, of a grey-white mineral which broke with a hackly fracture to show a glassy, colourless interior and one very poor cleavage. Refractive indices in sodium-light are: α 1·560, β 1·570, γ 1·584. By direct measurement with a spindle-stage, $2V\gamma = 81°$. One optic axis is nearly perpendicular to the poor cleavage. These optic data agree closely with Meixner's values for görgeyite. There was insufficient material for a chemical analysis, but X-ray fluorescence indicated sulphur, calcium, potassium and small amounts of strontium.

The X-ray powder pattern agreed only poorly with A.S.T.M. card 2–551 for $K_25Ca(SO_4)_6.H_2O$. Weissenberg photographs led initially to the following triclinic unit cell: *a*, 6·822 Å, *b*, 17·134 Å, *c*, 9·390 Å, α 90° 36′, β 111° 16′, γ 101° 24′, cell volume, 998·4 Å^3. The shortest axis showed two-fold symmetry in the zero- and upper-layer equi-inclination photographs, and oscillation photographs indicated a mirror plane perpendicular to it. The diffraction symmetry is hence $2/m$, and the true monoclinic unit cell has twice the volume of the triclinic cell above: *a*, 17·509 Å, *b*, 6·822 Å, *c*, 18·208 Å (all ± 0·008 Å), β 113° 16′, $a:b:c$ 2·567 : 1 : 2·669, cell volume, 1998 Å^3. Nefedov's first choice of unit cell was monoclinic, with *a*, 17·14 Å, *b*, 6·71 Å, *c*, 18·24 Å (from his *kX* values), β 114°, but he concluded that the symmetry arose from twinning and adopted a triclinic cell. We have seen no evidence of twinning.

Systematic extinctions observed were $(h + k)$ odd for the general reflexions hkl and l odd for the $h0l$ zone. The space group is therefore either Cc or $C2/c$, and as Mayrhofer determined the crystal class as $2/m$, the centrosymmetric space group may be assumed to be the true one. The statistical $N(z)$ test of Howells[6], which was made on the $h0l$ intensities, yielded a curve close to the hypercentric distribution and provides support for this choice.

The specific gravity of several clear fragments of the mineral was found by a flotation method to be 2·91 ± 0·01, which is close to the calculated value of 2·901 for four molecules of $K_25Ca(SO_4)_6.H_2O$ in our monoclinic cell, and to Nefedov's value of 2·93. Meixner's figure of 2·77 can be explained only by the presence of inclusions or extensive substitution by light cations.

The principal discrepancy between our own and the published data occurs in the cell dimensions. Although Nefedov's axial ratios are close to ours, we believe that the absolute values of the sides of his unit cell are in error, as the cell volume, chemical formula, and calculated density are discordant. There is some similarity between the two triclinic cells which were chosen, and their relationship to our monoclinic cell has been determined from a stereographic projection:

Astakós		Nefedov		
Triclinic	Monoclinic	Triclinic	Monoclinic	
a	$[0\bar{1}0]$	*a*	$[010]$	
b	$[1\bar{1}2]$	*b*	$[\bar{1}10]$	
c	$[\bar{1}10]$	*c*	$[\bar{1}12]$	probably
100	$\bar{1}11$	100	$\bar{1}10$	,,
010	001	010	$\bar{2}01$	,,
001	$\bar{2}01$	001	001	,,

As a check, particularly on the water-content, the salt $K_25Ca(SO_4)_6.H_2O$ ('pentasalt') was synthesized by Hill's[7] method and a thermogravimetric analysis confirmed that it contains only one H_2O per molecule. The powder pattern of the synthetic salt is identical with that of the

Astakós görgeyite, and hence the uncertainty in the water-content shown in the published data is resolved. Further, powder diffraction data were calculated from our single-crystal results of the monoclinic and triclinic cells, using an Elliott 803 computer with a programme written by Mr. D. J. Smith, and excellent agreement with the observed $\sin^2 \theta$ values was obtained. Neither of Nefedov's cells fitted our data. We are submitting our findings to the A.S.T.M. Powder Data File.

GEOCHEMISTRY

Relative Distribution of Thorium, Uranium and Lead estimated from the Isotopic Composition of Lead in Ores

IF the isotopic ratios $[^{206}\text{Pb}/^{204}\text{Pb}]_0$, $[^{207}\text{Pb}/^{204}\text{Pb}]_0$, and $[^{208}\text{Pb}/^{204}\text{Pb}]_0$ of primeval lead are known, the time t of formation of ore of lead (the present time = 0) and the present-day atomic ratios $[^{238}\text{U}/^{204}\text{Pb}]$ and $[^{232}\text{Th}/^{204}\text{Pb}]$ which would be observed in the original source of lead in ores can be estimated[1,2] from the measured isotopic ratios $[^{206}\text{Pb}/^{204}\text{Pb}]$, $[^{207}\text{Pb}/^{204}\text{Pb}]$ and $[^{208}\text{Pb}/^{204}\text{Pb}]$ by:

$$\frac{[^{206}\text{Pb}/^{204}\text{Pb}] - [^{206}\text{Pb}/^{204}\text{Pb}]_0}{[^{207}\text{Pb}/^{204}\text{Pb}] - [^{207}\text{Pb}/^{204}\text{Pb}]_0} = 138\,\frac{e^{\lambda_{238}T_0} - e^{\lambda_{238}t}}{e^{\lambda_{235}T_0} - e^{\lambda_{235}t}} \qquad (1)$$

$$[^{238}\text{U}/^{204}\text{Pb}] = \frac{[^{206}\text{Pb}/^{204}\text{Pb}] - [^{206}\text{Pb}/^{204}\text{Pb}]_0}{e^{\lambda_{238}T_0} - e^{\lambda_{238}t}} \qquad (2)$$

$$[^{232}\text{Th}/^{204}\text{Pb}] = \frac{[^{208}\text{Pb}/^{204}\text{Pb}] - [^{208}\text{Pb}/^{204}\text{Pb}]}{e^{\lambda_{232}T_0} - e^{\lambda_{232}t}} \qquad (3)$$

where λ_{232}, λ_{238} and λ_{235} are the decay constants of thorium-232 ($0{\cdot}499 \times 10^{-10}$/yr.), uranium-238 ($1{\cdot}54 \times 10^{-10}$/yr.) and uranium-235 ($9{\cdot}78 \times 10^{-10}$/yr.), 138 the isotopic ratio of uranium-238 to uranium-235 at present, and T_0 the age of the Earth ($4{\cdot}55 \times 10^9$ yr.). However, no attempt has been made to use these equations in order to determine the relationship, so far as distribution is concerned, of thorium, uranium and lead.

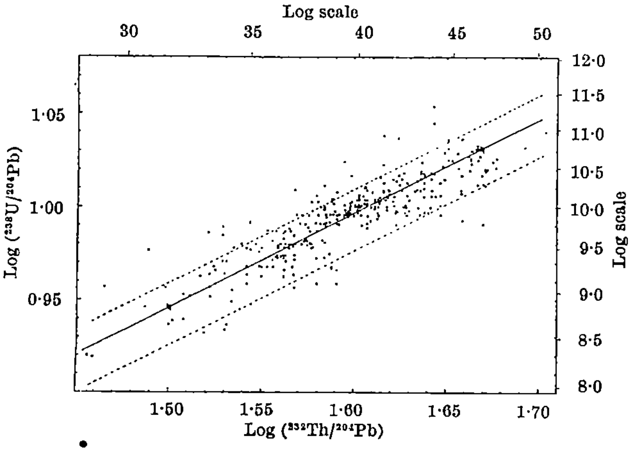

Fig. 1

In this communication the values estimated by me were used as the primeval lead, and the same data on common leads as used in the previous paper[3] were taken up again. The result of calculation is shown in Fig. 1. In this diagram, both co-ordinates are set on logarithmic scales, for a logarithmic scale rather than a direct scale seems to be tenable in general with the theoretical consideration[4,5].

As exemplified before[5,6], it will be of great value to quantitative or theoretical consideration to express the abundance relationship in a mathematical form. The application of least square method[3] to Fig. 1 yields the empirical formula:

$$\log\,[^{238}\text{U}/^{204}\text{Pb}] = 0{\cdot}503 \log\,[^{232}\text{Th}/^{204}\text{Pb}] + 0{\cdot}192 \qquad (4)$$

If the atomic ratios $[^{238}\text{U}/^{204}\text{Pb}]$ and $[^{232}\text{Th}/^{204}\text{Pb}]$ are reduced to the weight concentration ratios, we get:

$$\log\,(C_{\text{U}}/C_{204}) = 0{\cdot}503 \log\,(C_{\text{Th}}/C_{204}) + 0{\cdot}231 \qquad (5)$$

where C_{U}, C_{Th} and C_{204} stand for the weight concentrations of uranium, thorium and lead-204.

The distributional relationship with small deviations as seen in Fig. 1 is of much geochemical importance, because it appears to suggest that the abundances of minor elements in the material in which lead of ores originated have simple aspects at large. The empirical formula obtained here will be scrutinized in mathematical terms separately.

CHEMISTRY

Fluorescence of Organic Mixed Excimers

Birks and Christophorou[1], examining mixed excimers, reported that the sum of the fluorescence intensities from two solutions, one containing c moles of pyrene (component A) and the other c moles of 1-methylpyrene (B). is equal to the fluorescence intensity from a mixed solution containing c moles each of A and B.

The relation between the fluorescence intensity F of an excited dimer and the bulk concentration c is given (in the absence of other quenching processes) by the Stern–Volmer relation $Fc = F_\infty/(1 + c_h/c)$, where c_h is the mean self-quenching concentration[2].

If dimers are formed indiscriminately between compounds A and B, then F should follow the foregoing equation where c is now the total concentration of the solution. The direct proportionality between the intensity and the concentration as reported in ref. 1 is only possible when $c \ll c_h$. For $c = 5 \times 10^{-3}$ M, this requires $c_h = 0{\cdot}1$ M.

In oxygen-free *cyclo*hexane, c_h for pyrene is $7{\cdot}5 \times 10^{-4}$ or less[3]. In the presumably aerated solutions used in ref. 1, c_h would have been greater[4], though an increase to 0·1 M would be remarkable. Accordingly, we have investigated a similar system (pyrene and 4-methylpyrene) in aerated solution using the same concentrations as in ref. 1. We find the dimer fluorescence intensities of the mixed solution (c of A, and c of B) equal the average of the intensities of solutions of the pure substances at concentration $2c$, which in turn equals only 0·7 times the sum of the intensities of solutions of the pure substances at concentration c.

The inference is that mixed dimers are formed with the same probability and quantum efficiency as the pure dimers and that c_h in the presence of air is only about 8×10^{-3} M.

B. K. Selinger

Department of Physical Chemistry,
University of Sydney.

[3] Kasper, K., *Z. Phys. Chem.*, NF, 12, 52 (1957).

[4] Selinger, B. K., dissertation, Stuttgart (1964).

Dr. Selinger has directed attention to an unintentional ambiguity in our original communication. In comparing the fluorescence spectrum Z of the mixed solution, containing equimolar concentrations of A and B, with the sum $(A + B)$ of the fluorescence spectra of the two separate solutions of A and B, the relative quantum intensities of the monomer components of Z and $(A + B)$ were normalized. Reference to this standard procedure, which has been followed in other reports[1] of excimer fluorescence spectra from these laboratories, was unfortunately omitted. The ratio of the quantum yield of excimer fluorescence I_D to that of monomer fluorescence I_M is given by[2]:

$$\frac{I_D}{I_M} = \frac{q_D c}{q_M c_h}$$

where c is the molar concentration, c_h is the 'half-value' concentration, and q_M and q_D are the monomer and excimer fluorescence quantum efficiencies at $c = 0$ and $c = \infty$, respectively. For the normalized spectra, the excimer fluorescence intensity is proportional to I_D/I_M and hence to c. For the unnormalized spectra, I_D and I_M vary non-linearly with c, according to the Stern–Volmer relations[2]. Our original data[3], prior to normalization, agree closely with those reported by Selinger. They substantiate the conclusion, implicit in our previous communication, that mixed dimers of similar compounds are formed with the same probability and fluorescence quantum efficiency as the pure dimers.

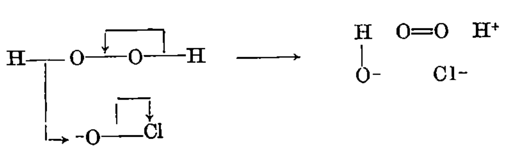
Chemi-luminescence as a Diagnostic Feature of Heterolytic Reactions which Produce Oxygen

The recent suggestions by Khan and Kasha[1] and by Ogryzlo *et al.*[2] that the emission of light which occurs during the interaction of hydrogen peroxide and sodium hypochlorite might be ascribed to singlet–triplet transitions of molecular oxygen have led us to examine the possibility that among those chemical reactions which yield molecular oxygen the heterolytic processes alone might prove to be chemi-luminescent.

By electron-pair movements, for example:



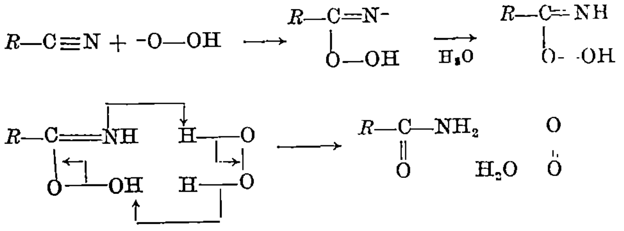
oxygen should initially be formed in a diamagnetic singlet state, whereas in reactions involving one-electron movements, for example:

$$\{Fe(CN)_6\}^{3-} + (:O—O\text{–}H)^- \longrightarrow \{Fe(CN)_6\}^{4-} + \cdot O—O\text{–}H$$
$$\{Fe(CN)_6\}^{3-} + \cdot O—O\text{–}H \longrightarrow \{Fe(CN)_6\}^{4-} + \cdot O—O\cdot + H^+$$

the oxygen should be formed in a di-radical, or triplet, state. Suggestions that heterolytic reactions might initially give activated forms of singlet oxygen, or that singlet–triplet transitions of molecular oxygen may need two oxygen molecules, are both irrelevant to this simple mechanistic differentiation between the two contrasting types of oxygen-producing reactions.

With the help of Dr. E. J. Bowen, who has put a sensitive photomultiplier at our disposal, we have found that other heterolytic oxygen-producing reactions are indeed chemi-luminescent.

While from the NaOCl—H_2O_2 reaction there is a short-lived emission of red light, from admixture of chloramine-*T* with neutral hydrogen peroxide the emitted light has both red and blue components. Singlet oxygen is formed in the reaction between alkaline hydrogen peroxide and nitriles; the mechanism of this[3] can be represented as:



When benzyl cyanide was used with 30 per cent hydrogen peroxide in alcoholic potassium hydroxide a bluish light, strong enough for visual observation in a darkened room, was emitted for 5–10 min. Examination with a photomultiplier and a red filter (Ilford 204) showed that this had a small red component. Acrylonitrile also gave strong emission of blue light, but with benzonitrile the emission was just detectable with the photomultiplier. A transient emission of light was also observed during the interaction of hydroxylamine with alkaline hydrogen peroxide.

No emission of radiation could be detected during the oxygen-producing reactions between hydrogen peroxide and $KMnO_4$, MnO_2, $K_3Fe(CN)_6$ and $Ce(SO_4)_2$, which are all one-electron-transfer processes.

We thank Dr. R. A. Lloyd of the Atomic Energy Research Establishment, Wantage, for assistance in some of the preliminary work.

Temperature Variation of β-Type Interlamellar Sorption Complexes of Graphitic Acid with Alcohols

Further investigations have been made of the β-type interlamellar sorption complexes formed by graphitic acid with normal alcohols[1-3]. We find that the formation of β-complexes (chain perpendicular to layer) or α-complexes (chain parallel to layer) with any given alcohol depends on the method of formation and pretreatment of the graphitic acid[4]. We have evidence that this statement may be true also for the α- and β-complexes of montmorillonite.

For the work recorded here, we selected one of the 'best' acids (that is, forming β-complexes most easily). We used a sample of graphitic acid dried at ambient temperature, and the same sample dried at 65° C. The complexes formed were examined by X-ray diffraction at ambient temperature, at +70° C and at −50° C. Results, in the form of a graph of basal spacing versus chain-length, are shown in Fig. 1.

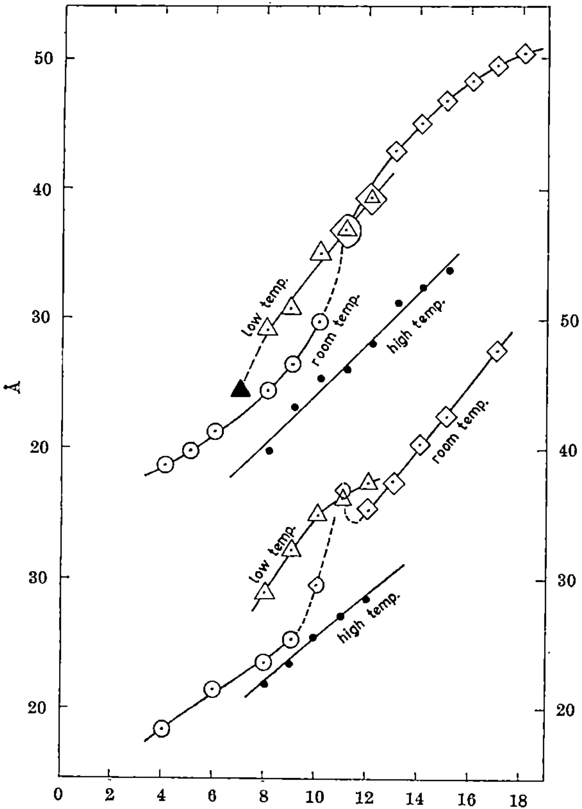

Fig. 1. Graphs of spacing versus chain-length for alcohols with graphitic acid. The upper series of graphs (left-hand scale) is for acid dried at room temp.; the lower series (right-hand scale) is for acid dried at 65° C. The type of plot indicates whether the sorbed alcohol is in the solid or liquid state, as indicated by the side-spacing line at about 4·3 Å. △, Solid, at −50° C; ◇, solid, at room temperature (18°–22° C); ▲, liquid, at −50° C; ○, liquid, at room temperature (18°–22° C); <), partly solid, partly liquid (or mixed), room temperature (18°–22° C); ●, liquid, at 70° C

From the presence of a side spacing at about 4·3 Å, in the form of a line or band, it can be determined whether the sorbed alcohol is in the solid or liquid form[5]. This information is indicated in Fig. 1. However, we suspect the solid–liquid transition is not a sharp one, and that intermediate forms exist.

It will be seen that at −50° C, the alcohols are generally in the solid form, and the observed spacing corresponds to that calculated for a fully extended chain. At +70° C, they are liquid, and give a lower spacing, presumably due to thermal motion. At ambient temperature a transition occurs, which takes different forms depending on the pre-treatment of the graphitic acid. The transition occupies a range and does not necessarily occur at the solidification point of the free alcohol. The 9-, 10- and 11-C alcohols at ambient temperature show anomalous diffuseness of the basal spacing, indicating interstratification, or other irregularities. We have evidence that at 70° C, the transition probably occurs in the region of octadecanol (normal m.p. 58·5° C).

The spacings for the pre-heated graphitic acid are generally lower than those for the acid dried at ambient temperature. The samples give only fully extended chains at low temperatures.

The slope of the graph for complexes with liquid alcohols is lower than that for the solid, presumably due to the influence of thermal motion. We have evidence (not all of which is presented here) that the solid–liquid transition becomes more marked as the temperature increases.

It should be noted that the formation of β-complexes is never complete, and that a proportion of unchanged graphitic acid exists in every case.

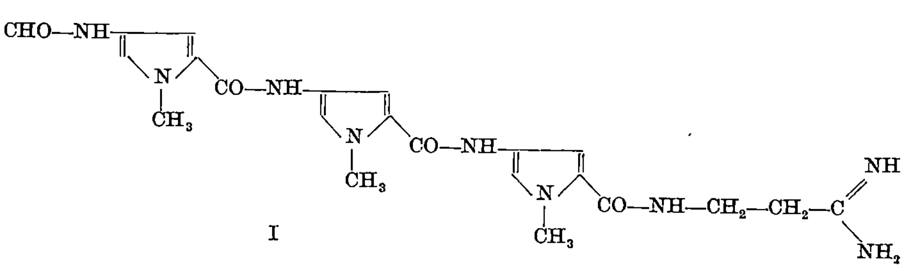
Structure and Synthesis of Distamycin *A*

Distamycin, a mixture of antibiotic substances exhibiting predominantly antifungal activity, was obtained by submerged fermentation and butanol extraction of the mycelial mass of a *Streptomyces* sp. An amorphous product (fraction *A*), showing a positive Ehrlich reaction and a typical ultra-violet spectrum, was separated from the other active components by solvent fractionation and chromatography on aluminium oxide[1,2]. Partially purified preparations of this fraction, obtained during isolation investigations, were found to inhibit in various degrees some experimental tumours in mice[3] and to interfere with the process of cell division *in vitro*[4]. The ultra-violet and infra-red spectra of these preparations showed some similarities with the antibiotic netropsin[5] (synonyms are antibiotic *T*–1384 (ref. 6) and congocidin[7]). Presence of the latter antibiotic in fraction *A* of distamycin could, however, be readily excluded by the lack of a positive Sakaguchi reaction and by direct chromatographic and spectroscopic comparison with an authentic sample.

The new basic antibiotic distamycin *A* is obtained in good yield as the hydrochloride (white to pale yellow crystals) when a few drops of 6 N hydrochloric acid are added to an aqueous solution of fraction *A*. The compound inhibits selectively the multiplication of phage *T*1 in *E. coli* K_{12} (ref. 8) and exhibits interesting antiviral and antimitotic properties. In this communication it is shown that distamycin *A* is β-{1-methyl-4-[1-methyl-4-(1-methyl-4-formylaminopyrrole-2-carboxamido)-pyrrole-2-carboxamido]-pyrrole-2-carboxamido}-propionamidine, corresponding to structure I.

Distamycin *A* hydrochloride, recrystallized from dilute-hydrochloric acid, melts at 184°–187° on the Kofler microscopic hot stage and is optically inactive. The crystals are firmly solvated; their composition, as deduced by elemental analyses after exhaustive drying, is $C_{22}H_{27}O_4N_9$.HCl. The ultra-violet spectrum in 96 per cent ethanol has maxima of absorption at 237 mμ (ε = 3 × 10⁴) and at 303 mμ (ε = 3·7 × 10⁴). The infra-red spectrum is consistent with the presence of an amidinium group (broad absorption band in the region 2,500–3,500 cm⁻¹ and peak at 1,690 cm⁻¹) and shows secondary amide bands at 1,660 and 1,630 cm⁻¹ indicative of a peptide-type structure.

Distamycin *A* was degraded by N hydrochloric acid in aqueous methanol to a diacidic base, crystallized as the

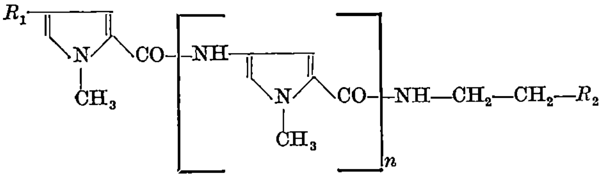


I

dihydrochloride $C_{21}H_{27}O_3N_9.2HCl$ (dec. slowly above 150°). On treatment with 0·2 N sodium hydroxide at room temperature the antibiotic gave one mole of ammonia and a neutral compound $C_{22}H_{26}O_5N_8$ (dec. 246°), with 95 per cent weight yield. Degradation of an amidine to an amide group was confirmed by the changes in the infra-red spectrum (the neutral compound does not show, *inter alia*, the 1,690 cm^{-1} band but exhibits a new amide band at 1,670 cm^{-1}, in addition to the secondary amide bands). Mild acid treatment of this neutral compound afforded a monoacidic base $C_{21}H_{26}O_4N_8$, isolated as its crystalline hydrochloride (m.p. 208°–210°). The new base shows an ultra-violet spectrum very similar to that of the antibiotic itself and to netropsinin (III, $R_1=NH_2$, $R_2=CONH_2$), the main degradation product of netropsin[6,9]. The infra-red spectrum shows absorption bands indicative of amine salt and of amide groups. Hydrolysis of the antibiotic with N sodium hydroxide in aqueous methanol gave two moles of ammonia and an amphoteric degradation product, isolated as its crystalline sulphate $C_{21}H_{25}O_5N_7 \cdot \frac{1}{2}H_2SO_4 \cdot 2H_2O$ (dec. 200°). Its infra-red spectrum exhibits absorption at 1,710 cm^{-1}, indicative of a carboxyl group.

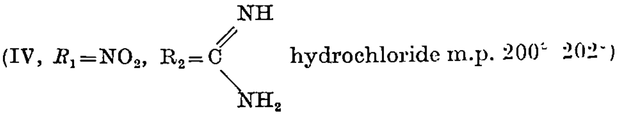
Prolonged treatment of distamycin *A* with 6 N hydrochloric acid at 120° and paper or thin-layer chromatography of the hydrolysate revealed the formation of β-alanine together with an unidentified ninhydrin reactive component. This component was also obtained when 1-methyl-4-aminopyrrole-2-carboxylic acid was subjected to the same acid treatment.

The C_{21}-monoacidic base was immediately related to the known netropsinin as follows. When netropsinin, obtained either by synthesis[10] or by degradation of the antibiotic netropsin, was condensed with 1-methyl-4-nitropyrrole-2-carboxylic acid chloride[10] in presence of aqueous sodium bicarbonate, and the resulting nitroamide (IV, $n=R_1=NO_2$, $R_2=CONH_2$; m.p. 260° dec.) hydrogenated catalytically, compound of structure IV where $R_1=NH_2$, $R_2=CONH_2$ was obtained and isolated as the hydrochloride, identified with the hydrochloride of the C_{21}-monoacidic base (identical melting point, infra-red and ultra-violet spectra and chromatographic behaviour). Formylation of the latter yielded a compound identical in all respects with the neutral degradation product. Therefore this substance has structure IV, where $R_1=CHO—NH$, $R_2=CONH_2$. Structure IV, where $R_1=NH_2$, $R_2=COOH$, is consistent with the properties of the amphoteric degradation product. From these investigations structure I was tentatively assigned to the antibiotic distamycin *A*. The nuclear magnetic resonance spectrum in deuterium oxide shows 20 protons as expected. A singlet at $\delta=7·76$ can be associated to the formamide group, a hypothesis in agreement with the fact that formic acid is liberated after alkaline hydrolysis of the antibiotic.



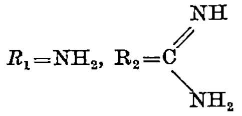
II, $n=0$; III, $n=1$; IV, $n=2$.

Structure I has been confirmed by synthesis. 1-Methyl-4-nitropyrrole-2-carboxylic acid chloride was allowed to react with β-aminopropionitrile in presence of aqueous sodium bicarbonate to give the nitronitrile of structure II, $R_1=NO_2$, $R_2=CN$ (m.p. 135°). This compound was then hydrogenated with palladium on charcoal in dimethylformamide to the corresponding aminonitrile which was condensed directly with the acid chloride to yield the nitronitrile of structure III, $R_1=NO_2$, $R_2=CN$ (m.p. 248°–250°). Catalytic hydrogenation to the corresponding amino derivative followed by condensation of the latter with the acid chloride gave the nitronitrile of structure II, $n=2$, $R_1=NO_2$, $R_2=CN$ (dec. above 270°). This compound was converted through the imidoester hydrochloride to the corresponding nitroamidine:



$$(\mathrm{IV},\ R_1=\mathrm{NO_2},\ \mathrm{R_2}=\mathrm{C}\begin{array}{l}{=}\mathrm{NH}\\ -\mathrm{NH_2}\end{array}\quad \text{hydrochloride m.p. } 200^\circ\text{–}202^\circ)$$

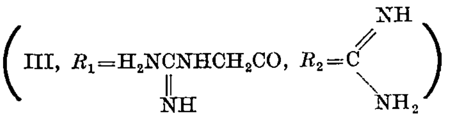
which, on hydrogenation with Adams catalyst in acetic acid, yielded the amino-amidine represented by IV where:



$$R_1=\mathrm{NH_2},\ \mathrm{R_2}=\mathrm{C}\begin{array}{l}{=}\mathrm{NH}\\ -\mathrm{NH_2}\end{array}$$

identical in all respects with the C_{21}-diacidic base obtained by mild acid treatment of the antibiotic. Formylation[11] of this compound gave the formylaminoamidine I. Its hydrochloride was identical by melting point, infra-red, ultra-violet and nuclear magnetic resonance spectra, chromatographic and electrophoretic behaviour, and degradation products, as well as by the biological properties with the antibiotic distamycin *A* hydrochloride.

Recently a similar synthesis of the antibiotic congocidin:



$$\left(\mathrm{III},\ R_1=\mathrm{H_2N}\underset{\underset{\mathrm{NH}}{\|}}{\mathrm{C}}\mathrm{NHCH_2CO},\ R_2=\mathrm{C}\begin{array}{l}{=}\mathrm{NH}\\ -\mathrm{NH_2}\end{array}\right)$$

has been described[12].

All compounds described in this communication gave correct elemental analyses and showed satisfactory spectroscopic properties.

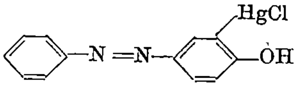
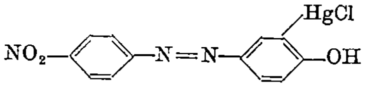
BIOCHEMISTRY

New Chromophoric Reagents for Labelling the Thiol Groups of Proteins

MANY methods have been proposed for the determination of thiol groups in proteins involving the direct attachment of a coloured moiety to the sulphydryl groups[1–7]. In one case at least[5], such a reaction has been used to introduce a coloured label on the SH group of a protein in order to facilitate the isolation of cysteine peptides and the determination of their amino-acid sequence. In this communication we report the synthesis and potential usefulness of two new azomercurials, 4-phenylazo-2-chloromercuriphenol (I) and 4-(*p*-nitro-



I



II

phenylazo)-2-chloromercuriphenol (II), which appear to offer certain advantages over previously reported chromophoric reagents of this type.

Compound I was prepared as follows. To 1·14 g of *o*-chloromercuriphenol[8], dissolved in 30 ml. of 15 per cent potassium hydroxide, were added 2·5 g sodium acetate, and the mixture was cooled to − 2°. This was followed by the dropwise addition of a solution of diazotized aniline composed of 0·32 g of freshly distilled aniline, 4 g of crushed ice, 1·7 ml. of concentrated hydrochloric acid and 0·25 g sodium nitrite. An orange-yellow precipitate was collected by filtration, thoroughly washed with distilled water, and finally dried over calcium chloride (yield 1·13 g). Further purification was achieved by passing a hot benzene solution of this product through a column of acid-washed alumina (Merck). After elution of a yellow impurity with benzene, compound I could be eluted with a mixture of benzene and ethanol (100 : 4). After evaporation of the solvent, the residue was recrystallized from hot benzene to give orange-yellow crystals (m.p. 146°–147°, uncorr.) anal.: calculated for $C_{12}H_9N_2OClHg$: C 33·2 per cent, H 2·1 per cent, Hg 46·4 per cent; found: C 32·3 per cent, H 2·2 per cent, Hg 45·7 per cent.

Compound II was prepared in essentially the same manner as compound I except that *p*-nitroaniline was used in place of aniline. Compound II was isolated in the form of orange-red crystals (m.p. 218°–220°) anal.: calculated for $C_{12}H_8N_3O_3Hg$: C 30·1 per cent, H 1·7 per cent, Hg 42·0 per cent; found: C 30·9 per cent, H 1·7 per cent, Hg 41·4 per cent.

Fig. 1 shows the reaction of various levels of cysteine with a constant level of compound I added in excess.

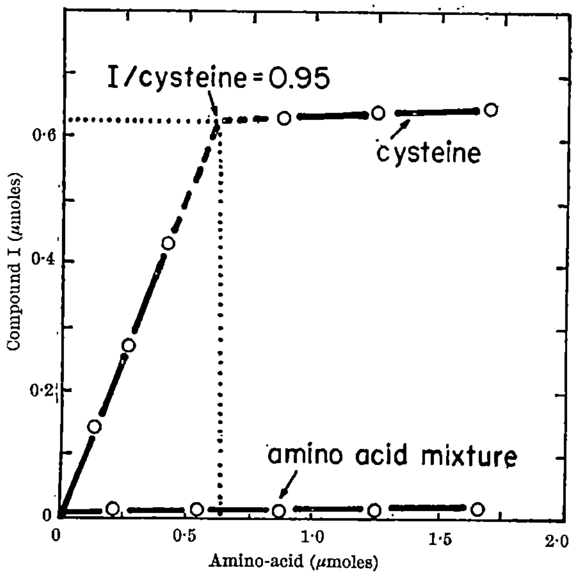


Fig. 1. Reaction of cysteine with compound I. To graded levels of cysteine, or a mixture of 18 amino-acids not containing cysteine, in 4 ml. 0·1 M phosphate buffer, *p*H 6·2, were added 6 ml. toluene containing 10 μmoles of compound I. After shaking for 1 min, absorbance of toluene layer was read at 350 mμ. Amount of compound I reacting with cysteine was calculated from difference in absorbance from control without cysteine and by reference to a standard calibration curve of compound I in toluene

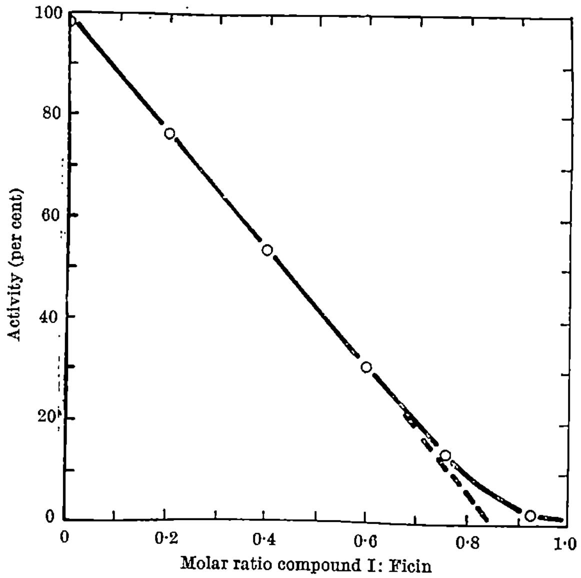

Fig. 2. Inhibition of ficin by compound I. To increasing amounts of compound I, dissolved in 1 ml. 0·085 M phosphate buffer, *p*H 6·2, containing 15 per cent ethyl alcohol, was added 1 ml. of the same buffer containing 0·08 μmoles of ficin. Activity was measured on casein (ref. 9) after incubation for 10 min at 37°. Activity in absence of inhibitor was taken as 100 per cent

The equivalence or breaking point of this curve indicates that compound I had reacted with cysteine in the expected molar ratio of 1 : 1. Similar results were obtained with compound II. As shown in Fig. 1, compound I did not react with any other amino-acid, thus establishing its specificity for the sulphydryl group.

The inhibitory effect of compound I on the activity of the sulphydryl enzyme, ficin[9], is shown in Fig. 2, where it is evident that the activity of ficin was completely lost at a level of 0·86 moles of compound I per mole of enzyme. This value corresponds quite closely to the expected value of 1 thiol group per molecule of ficin[9,10]. A similar experiment with compound II gave a value of 0·98. The reaction mixture from each of these experiments was subjected to dialysis and gel filtration on 'Sephadex *G*-50' in order to remove the last traces of the azomercurials, and then analysed for mercury[11]. These data showed that 0·65–0·70 mole of mercury per mole of protein had been incorporated, thus providing strong evidence for the formation of a mercaptide.

Apart from their ease of preparation, compounds I and II would appear to offer several additional advantages over the reagent, *N*-(4-dimethylamino-3,5-dinitrophenyl) maleimide (DDPM), proposed by Witter and Tuppy[5] for the labelling of SH proteins. Unlike DDPM, which is sparingly soluble in water, the azomercurials described here are quite soluble in aqueous media provided ethanol is present

Table 1. COMPARISON OF MOLECULAR EXTINCTION COEFFICIENTS (ε_M) OF CHROMOPHORIC REAGENTS FOR SULPHYDRYL PROTEINS

Compound	Solvent	λ_{max}	ε_M

* Determined in this laboratory on compound prepared according to Witter and Tuppy (ref. 5).

† Reported by Nosoh (ref. 7).

at a final concentration of 15 per cent, a condition not likely to precipitate or denature most proteins. Compounds I and II are also much more intensely coloured, especially in acid or base respectively, than DDPM or Nosoh's water-soluble azomercurial[7] (see extinction coefficients in Table 1) and hence should provide a much more sensitive indicator of any labelled peptides which may be isolated from derivatized proteins. The colour of peptides labelled with I or II separated by paper chromatography or electrophoresis could be considerably intensified by exposure to the fumes of concentrated hydrochloric acid or ammonium hydroxide.

Work is now in progress to test the applicability of compounds I and II for the labelling of SH proteins for the purpose of isolating cysteine-containing peptides.

This investigation was supported in part by research grant *GM* 04616 from the National Institute of General Medical Services, U.S. Public Health Service, and grant *G*13965 from the National Science Foundation.

L-Cysteine as Inhibitor of Potassium Retention by Brain Slices

L-Cysteine, in common with several other amino-acids, is able to inhibit the uptake of L-histidine by brain slices, but the inhibition which it produces, unlike that produced by the other amino-acids, is non-competitive[1]. It therefore appeared possible that cysteine might also have an inhibitory action on other transport phenomena. Its effect on the transport system for potassium, as indicated by alteration in the level of potassium in brain slices (normally maintained well above that of a suitable environment[2]), has therefore been investigated, and compared with the effect of other amino-acids.

The technique used was essentially similar to that described elsewhere, with similar precautions taken[1]. Slices of rat brain were incubated with agitation for 1 h at 37° C in Krebs's bicarbonate saline which contained the amino-acid under investigation. The tissue was then treated as described elsewhere[3] and the potassium estimated in tissue fluid by means of a flame photometer. There was no detectable alteration in the amount of any of the amino-acids in the suspending medium during the period of incubation, as judged by visual inspection of paper chromatograms[1]. (Reduced glutathione, which might be expected from its structure to have effects somewhat similar to those of cysteine, did show evidence of alteration in its nature and so has not been included in the series.) Cysteine did not interfere with the estimation of potassium when present at ten times the concentration of the latter. The *p*H of the suspending medium was measured at the end of all experiments and lay within the range 7·3–7·5.

The concentration of potassium in isolated tissue suspended in a suitable medium may be altered by the presence of amino-acids[2,4,5], but, as shown in Table 1, cysteine produced a greater reduction in the concentration of potassium in brain slices than did any of the other amino-acids investigated.

Table 1. Effect of Amino-Acids on Potassium in Brain Slices

Amino-acid added to suspending medium	No. of tissue samples for each amino-acid	Potassium concentration in tissue m.equiv./l.
None	24	46 ± 4
Glutamic acid	8	50 ± 3*
Aspartic acid	8	50 ± 4*
Taurine	8	49 ± 2
Tyrosine	8	48 ± 2
Alanine, glycine, proline, valine	6	47 ± 2 to ± 3
S-Ethyl-cysteine, histidine hydrochloride, methionine, phenylalanine	6 or 8	46 ± 1 to ± 5
S-Methyl-cysteine	10	44 ± 4
β-Alanine, leucine, 2-thiolhistidine, ornithine hydrochloride	8	44 ± 3
γ-Aminobutyric acid, cystine, tryptophan	8	44 ± 2
Lysine hydrochloride	10	43 ± 4
Arginine hydrochloride	8	43 ± 3
Cysteic acid	10	43 ± 3*
Cysteine hydrochloride	16	38 ± 3‡†

Amino-acids were of the L-form where applicable. Initial concentration of each amino-acid in suspending medium 2 mM. Figures shown for potassium concentration are mean and standard deviation. Incubation 1 h 37° C.

*$P < 0·05$, †$P < 0·001$: significance of difference from concentration of potassium with no added amino-acid. ‡$P < 0·01$: significance of difference from concentration of potassium in the presence of any of the other amino-acids used.

The effect of cysteine appears to be dependent on the presence of a free thiol group not attached to a resonating system. Those amino-acids containing a blocked thiol group (*S*-ethyl-cysteine, *S*-methyl-cysteine, cysteic acid, cystine and methionine) or in which the thiol group was attached to a resonating system (2-thiolhistidine) altered the concentration of potassium in the tissue relatively slightly or not at all.

Cysteine has been found to have a toxic effect on the intact animal[6] and on cultured tissue[7] and also to alter the activity of certain intracellular enzymes *in vivo*[8]. It is therefore likely, particularly in view of the non-competitive nature of its effect on L-histidine uptake, that the inhibitory effect of cysteine on the transport of both L-histidine and potassium is the result of interference with intracellular processes on which both types of transport are dependent.

Changes in the Fatty Acid Composition of Sebum associated with High Carbohydrate Diets

Excess of carbohydrate in the diet has been considered to be of significance in the ætiology of certain types of skin disorder[1]. With this in mind the opportunity was taken to examine the fatty acid composition of the sebum in subjects who were on experimental diets containing a relative excess of carbohydrate.

The subjects, seven adult males, were given an experimental diet consisting of 500 g of either sucrose or raw maize starch daily with *ad libitum* quantities of lean meat and green vegetables with vitamin supplements. The experimental diet was given for 25 days followed by 25 days on a normal free-choice diet, with a final 25 days on a diet which contained the alternative carbohydrate. Full details of the dietary intake are given elsewhere[2].

Samples of sebum were obtained on the 4, 11, 18 and 25 days of the diet by 'washing' the face at the end of a day with some cotton wool at the end of a wooden stick. The cotton wool was frequently dipped in a solution of equal parts of iso-propyl alcohol and petroleum ether (b.p. 40°–60° C). The lipid was extracted from the solution by the method of Hirsch *et al.*[3] and the proportion of each fatty acid was determined by gas-chromatography. Identification of all the peaks in the record was not attempted because some difficulty would have arisen in obtaining pure samples of each methyl ester. Presumptive identification only was made, based on the knowledge that the retention time in the gas-chromatograph is related logarithmically to the chain-length for each acid of the same degree of unsaturation.

The results (Table 1) showed first that a high carbohydrate diet altered the fatty acid pattern of the sebum, and secondly, that the nature of this alteration was dependent on the type of carbohydrate eaten. This was seen in the differences in the response between the starch and sucrose diets in the C16 : 0, C16 : 1 and C17 : 0 fatty acids in the sebum.

Table 1. PERCENTAGES OF THE FATTY ACIDS IN THE SEBUM ON CONTROL, STARCH AND SUCROSE DIETS

Fatty	Control		Starch diet			Sucrose diet		
acid	Mean	*S.E.* ±	Mean	*b*	*S.E.* ±	Mean	*b*	*S.E.* ±
12 : 0	0·7	0·09	0·7		0·05	0·6		0·07
14 : 0	5·3	0·28	4·6		0·25	4·9		0·24
14 : 1	3·5	0·19	3·1		0·14	2·9		0·27
15 : 0	5·4	0·26		−0·09	0·02		−0·07	0·03
15 : 1	2·7	0·23		−0·08	0·02		−0·06	0·02
16 : 0	22·7	1·20		+0·15	0·07	24·2		0·95
16 : 1	43·2	1·67	49·4		1·12		+0·31	0·14
17 : 0	3·6	0·37		−0·07	0·03	2·5		0·32
18 : 0	1·5	0·17	1·3		0·12	1·7		0·22
18 : 1	9·4	0·51	8·5		0·55	9·4		0·51
18 : 2	2·0	0·23	2·0		0·31	1·7		0·16

b, significant ($P < 0·25$) slope of line-percentage of fatty acid against time. *S.E.*, standard error.

It was expected that a relative excess of carbohydrate in the diet might be reflected in the composition of the sebum, but the finding that the type of dietary carbohydrate eaten exerts a qualitative influence on the sebum was not expected.

These changes in the fatty acid pattern of the sebum raise one point of biochemical interest, namely, the presence in sebum of appreciable amounts of fatty acids found only in low concentrations in the serum or adipose tissue, and support the findings of Weitkamp *et al.*[4], who reported odd-carbon numbered fatty acids in hair.

Reduction of Dehydroascorbic Acid by Animal Tissues

IT has long been known that an enzyme catalysing the reduction of dehydro-L-ascorbic acid (DHA) by glutathione to ascorbic acid occurs in plant tissues[1–3]. It can also be shown that DHA is in part reduced to ascorbic acid by animal tissues, although until recently no clear evidence was available to suggest that this is an enzymatic reaction. Recently, however, it has become clear that the reduction of DHA by hæmolysates of human erythrocytes occurs at a rate greater than can be accounted for in terms of a purely chemical reduction by glutathione[4,5].

Hæmolysates of erythrocytes from different species have now been examined for their ability to catalyse the reduction. The rate of reaction was measured in terms of the amount of ascorbic acid formed from dehydroascorbic acid in the presence of a standard amount of carbon monoxide-saturated hæmolysate. The preparation of the hæmolysate and the measurement of the ascorbic acid formed were carried out as previously described[5,6]. The catalytic effect of erythrocytes from the different species examined is given in Table 1, the µg of ascorbic acid formed in 30 min at pH 7·0 from 0·5 mg DHA in the presence of 1 mg of glutathione being taken as an index of the activity. At these concentrations of glutathione and DHA the chemical (that is, non-catalysed) reaction is virtually non-existent. The increased activity of the factor in cases of pernicious anæmia is of interest. It is now known that the activity of a number of enzymes in pernicious anæmia erythrocytes is increased in this way and to a comparable extent[5].

Table 1. FORMATION OF ASCORBIC ACID FROM DHA IN THE PRESENCE OF DIFFERENT HAEMOLYSATES

	Ascorbic acid formed (µg) (mean value for each species)
Human, normal (5)	31
Human, pernicious anæmia (5)	75
Kitten (2)	12
Bullock (2)	25
Sheep (2)	0
Mouse (4)	75
Rat (5)	252
Guinea pig (6)	270

µg ascorbic acid formed in 30 min at room temperature from 0·5 mg of DHA and 1 mg of glutathione in the presence of 12·5 ml. of carbon monoxide-saturated hæmolysate (≡2·5 ml. erythrocytes). The figures in brackets refer to the number of determinations made for each species.

Extracts of the liver of three species examined (rabbit, rat, guinea pig) also catalysed the reaction. *Active*, partially purified preparations have been made from guinea-pig liver. The fresh liver was ground with acid-washed sand in the presence of 0·9 per cent saline containing 0·001 per cent 'Tween 80' (50 ml. saline to each 20 g liver). The extract was centrifuged and the two semi-solid lower layers discarded. The reddish-brown upper layer was fractionated with ammonium sulphate at 10° C and the fraction separating between 52 and 66 per cent saturation collected. This was dissolved in the minimal quantity of 0·1 M phosphate buffer (pH 6·8) and dialysed overnight at 5° C against 0·01 M phosphate buffer (pH 6·8). Any solid matter separating out was removed by centrifugation and discarded. The preparation was stored at −20° C. In some cases the fractionation was repeated. The active fraction was retained by '*CM*-Sephadex *C*50' (a cation exchange material) but not by anion-exchangers such as DEAE-'Sephadex', thus suggesting its association

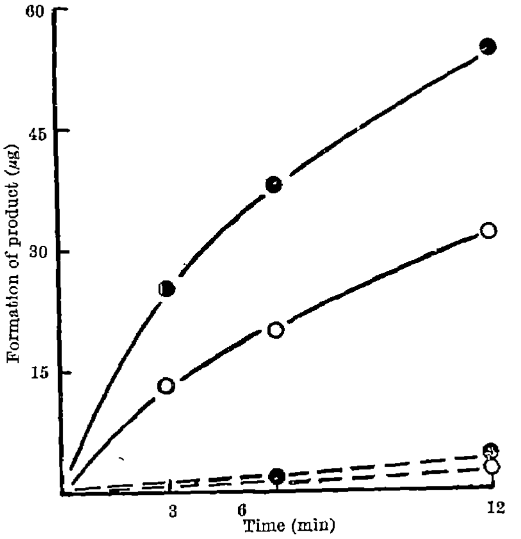

Fig. 1. Effect of the liver preparation on the formation of L-ascorbic acid (○) and D-isoascorbic acid (●) in the presence of glutathione. 1 ml. (2 mg) of glutathione and 0·6 ml. (1·2 mg) of DHA or DHisoA were allowed to react at room temperature in the presence of 2 ml. 0·2 M phosphate buffer, pH 6·3. ——, with 2 ml. of liver preparation; — —, with 2 ml. of water in place of the liver preparation

with a basic protein. Some preparations were further purified by running through DEAE-'Sephadex' columns buffered to *p*H 8·0; this removed a certain amount of non-active protein.

The preparation catalysed the reduction of DHA to ascorbic acid by glutathione. No reduction occurred in the absence of glutathione and the amount of ascorbic acid formed was directly proportional to the amount of liver preparation added. Dehydro-D-isoascorbic (dehydro-D-araboascorbic) acid was reduced more rapidly than DHA (Fig. 1). The preparation was inactive at *p*H values below 6·0 and appeared to have a maximum activity at about *p*H 7·0; activity measurements above *p*H 7·0 were difficult because of the increasing rapidity of the chemical (that is, non-catalysed) reaction with increase in *p*H above 7·0.

Azide, carbon monoxide and fluoride were without effect on the reaction at M^{-2} concentration. It was difficult to assess the effect of sulphydryl inhibitors because of their inhibition of the non-catalysed reaction. Dialysis for 20 h against 0·01 M phosphate buffer (*p*H 6·8) at 5° C increased the activity by 20 per cent; 0·1 per cent EDTA had a similar activating effect. Heating the preparation for 6 min at 98° C resulted in a 50 per cent loss of activity.

It would therefore appear that there is present in animal tissues a factor catalysing the reduction of DHA to ascorbic acid in the presence of glutathione. Its comparative resistance to destruction by heat is in contrast with results obtained for the corresponding plant enzyme[2]; it is, of course, known that certain partially-purified enzymes are markedly thermostable[7,8].

Bone Growth and Uptake of Radiocalcium in Tetracycline-treated Rats

THE selective localization of tetracyclines in mineralizing tissues has prompted consideration of possible untoward skeletal effects associated with their use in medical practice. Commanding attention in this respect are investigations in human beings showing that exposure to these antibiotics during tooth formation produces hypoplasia of the dental enamel[1–5]. It has also been reported that tetracycline can interfere with the growth of the long bones in infants[6,7]. Moreover, there is evidence that these agents can impair fracture healing in dogs[8] and can adversely affect mineralization in a wide range of animal forms including the larval sand dollar[9], a teleost fish[10], the chick embryo[11], a marine mollusc[12] and the rat[13,14].

This communication reports the results of work designed to investigate the effect of graded doses of tetracycline on bone growth and on the skeletal and dental uptake of radiocalcium in rats.

Twenty-one day-old male Sprague–Dawley rats were randomly assigned to groups (I–IV) and given intragastrically 1·0 ml. of distilled water (I) or 1·0 ml. of an aqueous solution containing either 1·0 mg (II), 5·0 mg (III), or 20·0 mg (IV) of oxytetracycline hydrochloride (courtesy of Chas. Pfizer and Co., Inc., New York) on each of ten consecutive days. All received intraperitoneally 1·0 ml. of a solution (*p*H 6·8) containing 5 μc. of calcium-45 and 10 μg of calcium (as the chloride) 1 h after each intubation. The rats were housed individually and fed a commercial laboratory chow.

Four hours after the final injection the rats were killed and one femur, the lower incisors, and the third molars were excised from each. This molar was selected since the bulk of the enamel and crown dentine is deposited between 20 and 25 days of age[15]). The femurs were measured proximally–distally with a micrometer, then extracted in alcohol (4 h) and in ether (8 h). All samples were incinerated overnight at 550° C and the ash of each dissolved in hydrochloric acid and analysed for calcium-45[16].

Gain in body-weight (mean g ± *S.E.*) was: I, 40·8 ± 2·4 (10 rats); II, 38·6 ± 1·9 (11 rats); III, 44·3 ± 3·1 (11 rats); and IV, 45·5 ± 2·9 (10 rats). None of these values differs significantly ($P > 0.05$) from one another. The mean length (mm) of the femurs of these same animals at termination was: I, 21·76 ± 0·21; II, 21·41 ± 0·26; III, 21·80 ± 0·25; and IV, 21·80 ± 0·17. Again, these values were statistically indistinguishable. The mean length of the femur at 21 days of age was 16·99 ± 0·11 mm based on measurements obtained with a group of 15 comparable rats. This lack of effect of tetracycline on the growth of long bones in rats is in contrast to the results of work on a human being cited earlier[6], where radiographic estimation of fibular growth in normal premature infants receiving tetracycline indicated a 40 per cent mean inhibition during the period of administration (9–12 days). It is noteworthy that Group IV rats received two and a half to five times more tetracycline per kilogram of body-weight (approximately 0·50 g/day at the start to 0·25 g/day at death) than did these same children (0·1 g/day).

Comparison of femur ash weights (Table 1) by analysis of variance also gives no indication that tetracycline affected bone mass or, for that matter, the ash weight of the incisor and molar teeth. Indeed, previously unreported findings from another experiment[17] indicated that the femurs of rats fed a diet containing 0·01 per cent of oxytetracycline hydrochloride for 100 days weighed more ($P < 0.01$) than those of the controls, namely, 432·5 ± 10·1 mg (13 rats) as compared to 362·7 ± 13·6 mg (13 rats) expressed on the dry, fat-free basis. The ash content (per cent) of these same bones was also higher ($P < 0.01$), being 57·68 ± 0·33 and 55·53 ± 0·73 for the tetracycline-supplemented and control rats, respectively. Of interest in this connexion are reports that the administration of chlortetracycline increased skeletal growth in young calves[18]. In rachitic rats, an increased calcification response to vitamin D[19] and a higher bone ash concentration[20] were reported. In the work recorded here the ash per cent of the femurs, incisors, and molars (Table 1) was unaffected by tetracycline. These different responses to tetracycline administration may possibly be related to nutritional status since the incorporation of chlortetracycline into purified diets adequate in all known dietary essentials except calcium caused no increase in body-calcium retention by growing rats[21].

Table 1. EFFECT OF TETRACYCLINE ON ASH CONTENT AND RADIOCALCIUM UPTAKE OF RAT FEMURS, INCISORS, AND MOLAR TEETH *

Sample	Tetracycline (mg/day)	No. of samples	Ash weight (mg)	Ash (%)	Calcium-45 (total % dose)
Femur	0·0	10	52·20 ± 1·88	42·40 ± 0·56	2·60 ± 0·084
	1·0	10	56·87 ± 1·25	44·94 ± 0·38	2·37 ± 0·096
	5·0	11	55·82 ± 2·17	44·32 ± 0·45	2·69 ± 0·057
	20·0	10	53·50 ± 1·86	43·84 ± 0·94	2·41 ± 0·082
Lower incisors	0·0	10	28·21 ± 0·59	66·94 ± 0·70	1·06 ± 0·044
	1·0	9	30·16 ± 0·60	68·99 ± 0·34	0·90 ± 0·031
	5·0	11	29·01 ± 0·64	67·89 ± 0·45	1·02 ± 0·061
	20·0	10	27·79 ± 0·64	66·72 ± 0·41	1·04 ± 0·029
Third molars	0·0	10	9·59 ± 0·38	74·22 ± 1·23	0·50 ± 0·029
	1·0	10	10·54 ± 0·33	73·44 ± 0·65	0·45 ± 0·046
	5·0	11	9·41 ± 0·37	70·71 ± 0·80	0·50 ± 0·031
	20·0	11	9·81 ± 0·28	75·31 ± 0·85	0·48 ± 0·011

* All values expressed as mean ± *S.E.*

Radiocalcium uptake by the different samples is shown in Table 1. (Data are expressed as percentage of total dose retained since comparison of total ash weight with total dose showed no correlation within groups.) In each case examination of the results by analysis of variance revealed no significant differences ($P > 0 \cdot 05$) attributable to tetracycline administration. There is general agreement that the fixation of radiocalcium by the mineral phase of calcified tissues occurs through its incorporation in forming crystals and by isoionic surface exchange with pre-existent crystals; the amount of isotope retained is the result of these processes and that of resorption. It has previously been shown that, in young growing rats, resorption associated with skeletal remodelling of the long bones has little or no effect on the retention of previously fixed radiocalcium for a period of time in excess of that used here[22]. It would follow from this that the radiocalcium content of the femur reflects the processes of mineral accretion and exchange and not resorption. Certainly this is the case with the incisor and molar teeth since these structures are not subject to resorption. One must conclude that under the present experimental conditions, at least, tetracycline administration had no effect on the uptake of radiocalcium by either bone or teeth. Considering the pharmacological importance of these agents there is, we believe, an important need for further assessment of their role in calcification.

Location of Glyceraldehyde-3-phosphate Dehydrogenase in Starch-gels

SPECIFIC staining reactions have been used to locate several enzymes in starch-gels after the electrophoresis of crude enzyme extracts, and these techniques have been used to detect molecular variants of these enzymes[1–3]. This communication reports a technique for staining glyceraldehyde-3-phosphate dehydrogenase, an important enzyme in intermediary metabolism, and some results obtained in the electrophoresis of preparations from strains of streptococci.

The micro-organisms were grown either in a synthetic medium[4], or in a broth containing 1 per cent glucose, 0·4 per cent sodium chloride, 0·5 per cent yeast extract (Difco), and 1 per cent proteose peptone (Oxoid). The cultures were incubated at 37° C for 24 h, and the cells gathered by centrifugation at 2,000*g* for 15 min, re-suspended in an equal volume of water and re-centrifuged. The bacterial pellets were then suspended in distilled water (about 200 mg wet weight/ml.) containing 1 mg of cysteine hydrochloride. Disintegration of the cell-walls was effected by shaking this suspension with an equal volume of glass ballotini[5] (Jencons, grade 11) for 20 min using a Griffin flask shaker at its maximum rate of oscillation. The beads were filtered using a sintered-glass funnel (porosity No. 2), and the slightly opalescent filtrate centrifuged at 10,000*g* at 0° C for 30 min. Electrophoresis of this extract was carried out as described by Fildes and Parr[3], using about 10 V/cm for 1 h, in a gel prepared in 0·01 M phosphate buffer of *p*H 7·0. The gels were sliced horizontally and stained on the cut surface. The staining mixture was prepared by incubating 1 mg of aldolase (Sigma Co.) with 50 mg of fructose-1 : 6-diphosphate disodium salt in 1 ml. of 0·1 M *p*H 7·5 *tris* chloride buffer for 30 min at 37° C, and then mixing this preparation with 9 ml of 0·1 M *p*H 8·5 *tris* chloride buffer in which was dissolved 100 mg of agar, 2 mg of NAD, 2 mg of the tetrazolium salt 'MTT', 0·4 mg of phenazine methosulphate, and 15 mg of sodium arsenate. The temperature was about 45° C when this mixing was carried out, and the whole was immediately poured on to the starch-gel when it set as a clear pale yellow layer. After incubation at 37° C for about 0·5 h the positions of the enzymes were revealed by dark-blue bands.

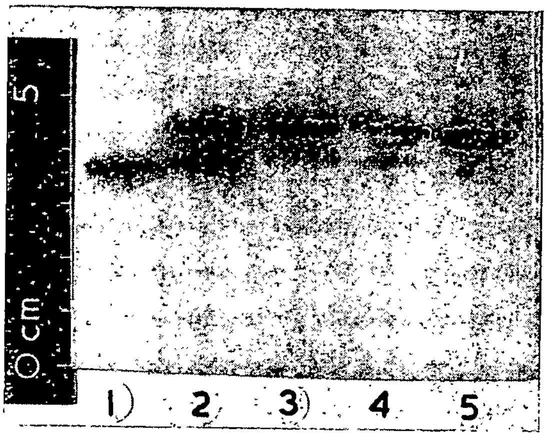

Fig. 1. Starch-gel electrophoresis of glyceraldehyde-3-phosphate dehydrogenase of five Group *D Streptococci*

Fig. 1 shows the results of applying this method to *Streptococcus faecalis HT*25 isolated from human dental plaque (sample 1), *Streptococcus faecalis* N.C.T.C. 775 (2), N.C.D.O. 580 (3), and N.C.D.O. 582 (4), and *Streptococcus zymogenes* N.C.I.B. 8886 (5). All strains show two isoenzyme fractions, those of *HT*25 being so close together as to appear as one band in some instances. In the other four strains the two components are more widely separated. The stain is equally intense in both bands of N.C.T.C. 775, but the other three strains show a higher activity in the faster moving fraction. Hence there are strain differences in the isoenzymatic forms of this enzyme among the group *D Streptococci*.

Similar results have been obtained by using glyceraldehyde-3-phosphate derived from its diethylacetal, and also by using a different enzymatic preparation of this material[6]. The method described gave a staining reaction with a commercial preparation of glyceraldehyde-3-phosphate dehydrogenase.

There have been several attempts to subdivide the streptococci on the basis of various biochemical reactions, but such classifications have evident shortcomings[7]. Recently it has been shown[8,9] that the *faecalis* group comprises a continuous spectrum of biotypes, and that the named subdivisions, *zymogenes*, *liquefaciens*, etc., are by no means species, but represent types which have the more common combinations of the biochemical properties used in the attempted classifications. The results reported here, and those of the electrophoresis of other enzymes, indicate that besides the variation in constitutive enzymes implied above, there is also heterogeneity of isoenzymatic forms among various strains of this group of micro-organisms.

PHYSIOLOGY

Potassium Effects on Cæsium – Choline Interactions in Muscle Membrane

In an earlier paper it was shown that addition of small concentrations of choline ion to bathing solutions which already contain cæsium significantly reduces the resting membrane potential of frog sartorius muscles[1]. The work recorded here is an extension of this investigation, and is concerned with the following questions : (*a*) Are the combined effects of cæsium and choline on the membrane potential reversible ? (*b*) To what extent does potassium affect the cæsium–choline interaction ? (*c*) Does the entire muscle cell surface participate in the cæsium–choline interaction ?

Experimental procedures were similar to those already described in ref. 2. Sartorius muscles from *Rana pipiens* were dissected so as to leave the lower side practically free of connective tissue, and the nerves were cut as close to the muscle surface as possible. Individual muscles were mounted in a 500-ml. 'Lucite' chamber at 120 per cent of resting length by means of a special holder and micrometer system. Bathing solutions were made up by adding cæsium, potassium or choline chloride in appropriate amounts to standard potassium-free Ringer's formula (112 mM NaCl, 1·89 mM $CaCl_2$, 2·5 mM Na_2HPO_4, 0·5 mM NaH_2PO_4). In some experiments, 300 units/ml. of hyaluronidase were added to the indicated solution. All experiments were carried out at 25° C. Twenty pairs of muscles were used in each experimental solution. Only potentials which developed instantaneously with microelectrode penetration were recorded and used in the data. Each point shown in Figs. 1 and 2 is the average of potential measurements on 180 cells.

Muscles were scanned by mounting the microelectrode assembly in a modified *X–Y* plotter which laid out a pattern of electrode positions in steps of 200μ.

The results are summarized in Figs. 1 and 2. It is clear from Fig. 1 that the depolarizing effect of 10 mM choline in 2·5 mM cæsium–Ringer is *not* reversed when the muscle is washed with choline-free cæsium–Ringer, but is reversed when the muscle is washed with normal (2·5 mM potassium) Ringer. In the absence of cæsium, choline produces no depolarization, in agreement with earlier work (Fig. 2*A*). In the presence of both potassium and cæsium, the depolarization by choline is less than in cæsium without potassium (Fig. 3). The fractional depolarization (ratio of resting potential before addition of choline to resting potential in presence of choline) produced by 10 mM choline is 1·27 in 2·5 mM cæsium–Ringer, but only 1·15 in Ringer containing both 1·25 mM cæsium and 1·25 mM potassium. Treatment with hyaluronidase does not alter the depolarization produced by 10 mM cæsium–Ringer, and the fractional depolarization produced by 10 mM choline under these conditions is still 1·27 (Fig. 2*B*). Although not shown in each figure, all these effects are reversible and repeatable. The lack of time dependence of all the potentials over periods of several hours is also noteworthy.

The results of the scanning studies were negative : no significant differences were obtained in potential measurements from different regions of a single muscle fibre. End-plate regions could be identified visually under the microscope, and several electrode penetrations were achieved in each such region.

The interactions between cæsium, potassium and choline suggest the following working hypothesis. Suppose that receptor 'sites' or 'configurations' to which choline can attach in some way are present on the cell surface, and that the result of the attachment of choline to these sites is a decrease in measured membrane potentional. Potassium interferes with this choline-receptor interaction, and cæsium enhances it. The stability of the choline depolarization in cæsium–Ringer, especially after washing off excess choline, indicates that choline reacts in an all-or-none fashion when cæsium is present. The potassium effects also require us to conclude that the sites are on the 'outside', since choline on the 'inside' would be prevented from binding by the high levels of intracellular

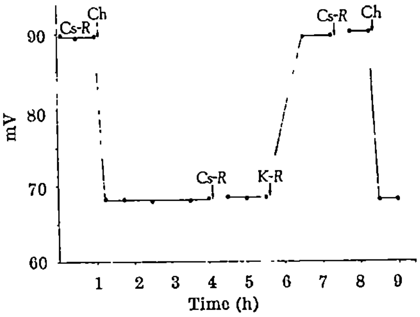

Fig. 1

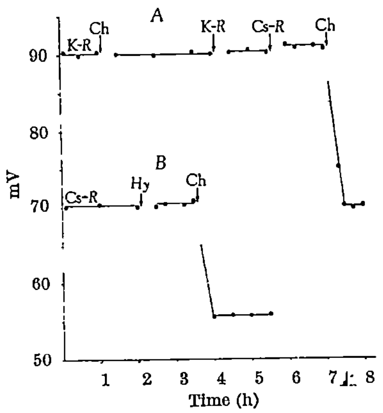

Fig. 2

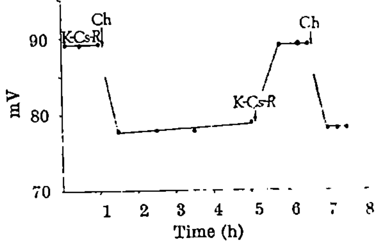

Fig. 3

Figs. 1, 2 and 3. Measured membrane potentials in millivolts plotted as a function of time, with the muscles bathed in solutions indicated by the letter symbols as follows: Cs-*R*, 2·5 mM cæsium–Ringer, except in Fig. 2*B* where the Cs concentration was 10 mM; K–*R*, 2·5 mM potassium Ringer; Ch, indicated solution made up to 10 mM in choline chloride, and applied at times indicated by vertical arrows; K–Cs–*R*, potassium-cæsium–Ringer, 1·25 mM K and 1·25 mM Cs in the same solution. *Hy*, 300 units of hyaluronidase per ml. added to the indicated solution. Times at which solutions were changed are indicated by vertical arrows potassium. Both cæsium and choline have been shown to enter the cell under our experimental conditions[1,3].

Are the postulated receptors for choline identical with the widely accepted acetylcholine receptors implicated in motor end-plate function[4,5]? Much more work is needed to clarify this situation, but the fact that excess external potassium results in liberation of acetylcholine from nerve endings is suggestive[6,7]. However, the apparent independence of the cæsium–choline depolarization from external sodium concentration, at least over the range 56–112 mM sodium chloride[1], is puzzling, since it prevents us from explaining the measured potential decrease as a result simply of increased sodium permeability. Sensitivity to acetylcholine is normally restricted to the motor end-plate region, but spreads over the whole muscle surface after denervation[8,9]. This spreading out process does not begin for at least 8 h after denervation, however (15 h under our laboratory conditions), so it is not likely to be involved in these choline effects. The scanning results indicate that the ability to react with choline is distributed over the entire muscle cell surface, including the motor end-plate region, but not limited to it.

Lack of Artificial Acclimatization to Heat in Physically Fit Subjects

DURING investigations of artificial acclimatization to heat on three physically fit subjects, the usual changes in sweat rates, rectal temperatures and pulse rates were not observed. The acclimatization procedure consisted of five 2-h walks on an every-other-day sequence. The daily protocol was 50 min walking at 6·4 km/h on a level treadmill and 10 min rest each hour. The environmental conditions were dry bulb weight = 49° C, wet bulb weight = 28° C, and globe temperature = 49° C. Comparing the results of walk 1 with walk 5, the average pulse rate decreased 1 beat/min; the sweat rate decreased 66 g/h, and the rectal temperature decreased 0·3° C.

Other workers have shown that the major physiological changes occur after four or five exposures[1–3] and the optimal exposure time was 100 min[4]. It was hypothesized that the physiological changes induced in the subjects as a result of their high level of physical fitness precluded any heat effects. Thus the subjects were able to perform as though they were acclimatized to heat.

The question then arises when conducting heat acclimatization investigations that utilize physical exercise: which changes are due to environmental stimuli and which are due to the exercise? A further complication is that, since exercise also produces heat, what is the relationship between exercise heat and environmental heat on the response of the subject. Fox *et al.*[5] have recognized the possible separate effects of environment and exercise and commented that "a part of the large decrease in pulse rates normally observed when using the conventional technique (of heat acclimatization) may be due to the improved cardiovascular efficiency consequent on the repeated performance of a particular physical exercise. . . ."

In understanding the mechanisms of heat acclimatization it seems imperative that cognizance be taken of the level of physical fitness of the subjects as well as the relative contributions of the separate effects of the particular exercise and environment.

Direct Evidence for an Action of Acetylcholine on Motor-nerve Terminals

SOME twenty-five years ago Masland and Wigton[1] showed that antidromic action potentials could be recorded from the ventral roots of cats during the muscular contraction provoked by the intra-arterial injection of acetylcholine. As a result of these experiments they suggested that acetylcholine might have an excitant effect on motor-nerve terminals. Later work[2] has shown that many other quaternary ammonium compounds have the same ability to provoke antidromic action potentials in motor nerves. In particular Werner[2] has shown, by ingenious but indirect means, that these drug effects are not due to excitation of the terminals by synchronous muscle action potentials. Despite these experiments which seem most satisfactorily explained by the presence of some cholinoceptive sites on the nerve terminals[3], it has recently been claimed that at the present time there is no direct evidence for an action of acetylcholine on motor-nerve terminals[4]. This problem is of special interest, for an excitant action of the acetylcholine released by nerve impulses on nerve terminals is the central feature of a new hypothesis of transmitter release at ganglionic and neuromuscular junctions put forward by Koelle[5]. This excitant action is thought to release further acetylcholine in a sort of positive feed-back action.

In the investigation recorded here the effect of muscle activity was eliminated by using rat diaphragm-phrenic nerve preparations *in vitro*, paralysed with either *d*-tubocurarine (Burroughs Wellcome) or an excess of magnesium chloride in the bathing Krebs–Ringer solution. The problem of acetylcholine action was attacked directly, using the methods developed by Hubbard and Schmidt[6] for stimulating nerve terminals. As in that investigation the terminals were located by the preliminary recording of extracellular miniature end-plate potentials in magnesium-poisoned preparations or by the recording of focal end-plate potentials in curarized preparations. The recording microelectrodes were filled with 4 M sodium chloride and had 1·5–3μ tips and 1–3 MΩ resistance. Stimulating pulses of 0·1 msec duration from a Grass isolation unit were then applied through the same electrodes and the single all-or-nothing antidromic impulses set up by the stimulation were recorded in the phrenic

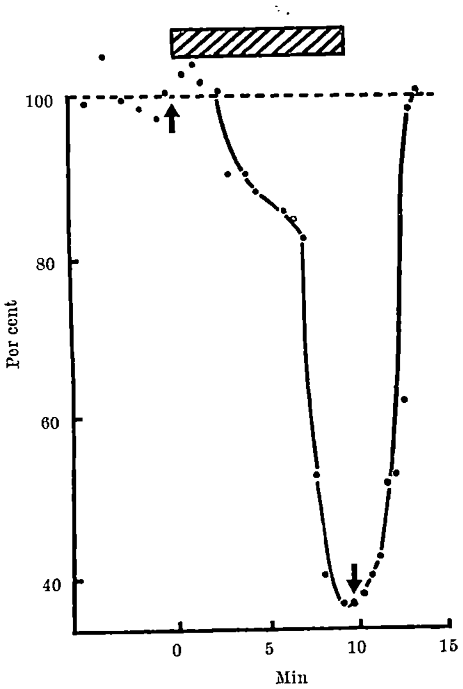

Fig. 1. The effect of acetylcholine on the threshold of motor-nerve terminals in a curarized preparation. The dots indicate threshold, that is the amplitude of current pulses adequate to evoke antidromic action potentials in 2–4 of six trials when applied in the vicinity of motor-nerve terminals. Threshold (ordinate) is expressed as a percentage of the average threshold before the introduction of acetylcholine (dotted line, 100 per cent). At time 0 (abscissæ) acetylcholine 10^{-7} g/ml. was introduced (marked by first arrow and the beginning of the hatched bar). After a big fall in threshold the acetylcholine was washed out (arrow and end of hatched bar). The threshold then progressively returned to the control value. The temperature was 35° C and all solutions contained *d*-tubocurarine chloride in a concentration of $1\cdot8 \times 10^{-6}$ g/ml. and prostigmine chloride in a concentration of 10^{-6} g/ml.

nerve with a pair of platinum electrodes. The threshold of the terminals was assessed by recording the stimulating pulses across a 50Ω resistance in the stimulating circuit and measuring, from filmed records, the pulse amplitude necessary for setting up antidromic impulses. Under the experimental conditions a 95 per cent exchange of solutions took 3–4 min.

Fig. 1 illustrates a typical experiment in which the control solution contained *d*-tubocurarine chloride ($1\cdot8 \times 10^{-6}$ g/ml.) and prostigmine chloride (10^{-6} g/ml.). The average pulse amplitude required to elicit antidromic action potentials is shown as 100 per cent and indicated by the dotted line in the graph. At the time marked by the arrow and the beginning of the hatched bar the perfusing fluid was changed to a solution differing only in that it contained acetylcholine chloride (A. G. Fluka) in a concentration of 10^{-7} g/ml. Three min later there was an abrupt fall in the pulse amplitude required to set up antidromic impulses. By 9 min effective pulses were only 37 per cent of the control strength, and after 9·5 min the acetylcholine was washed out with control solution (arrow and end of hatched bar). Within 30 sec of the change of solution the threshold had risen and after 4·5 min of washing the threshold had returned to the control value. Similar results have been observed in many other curarized and magnesium-paralysed preparations. Preliminary experiments indicate that this fall in threshold is the result of the stimulation of a typical cholinoceptive system, for the effect of acetylcholine is antagonized by curare and increased by prostigmine.

These results thus provide direct evidence for a depolarizing action[7] of acetylcholine on nerve terminals. This depolarization could generate action potentials by a local circuit action involving nearby nodes of Ranvier. At first sight these results also support Koelle's hypothesis. However, the experiments of Ciani and Edwards[8] indicate that perfusion with acetylcholine reduces the number of quanta of transmitter released by nerve stimulation at frog neuromuscular junctions *in vitro*. We have made similar observations at junctions in the rat diaphragm. This reduction in transmitter output is presumably a consequence of the depolarization of the terminals. Action potentials in the depolarized terminals would be reduced in size and thus have a reduced ability to liberate transmitter[9]. It would appear therefore that the physiological action of acetylcholine on nerve terminals is a negative feed-back on further acetylcholine release rather than the positive feed-back postulated in Koelle's hypothesis.

Concentration of Ammonia in the Gastric Venous Blood of Dogs during Acid Secretion

AMMONIA has been detected in gastric juice during acid secretion in response to parenteral histamine in many species, including man and dog[1–4]. This has been attributed to the action of urease in the gastric mucosa on endogenous urea[4,5]. Conflicting observations have been made as to whether ammonia is also released into gastric venous blood during acid secretion[6,7]. Turner[6] found a

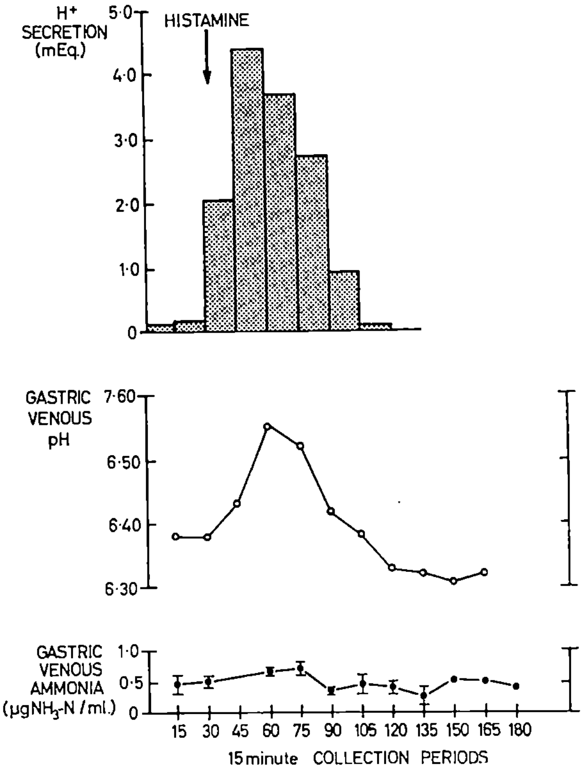

Fig. 1. Gastric venous ammonia concentration following subcutaneous histamine. The range of duplicate estimations of ammonia concentration is indicated

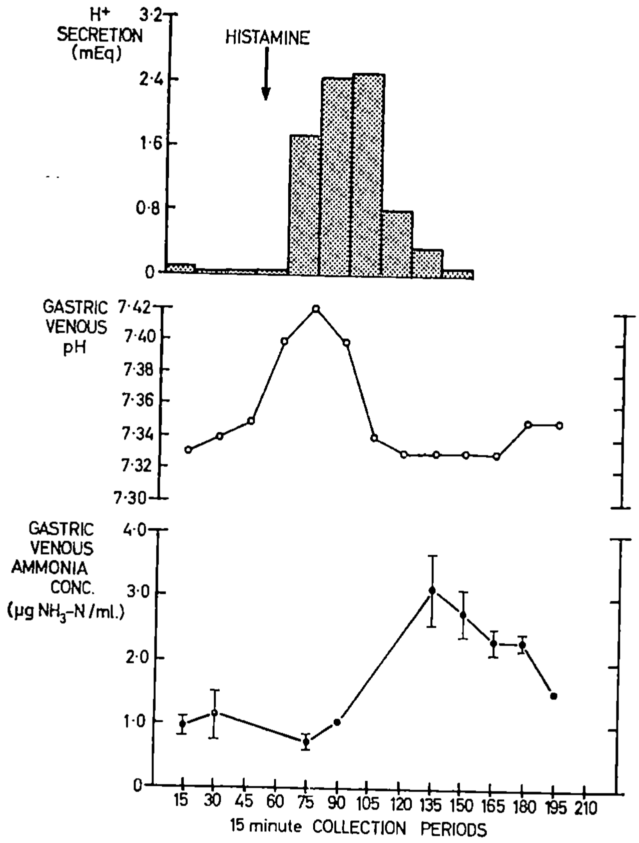

Fig. 2. Gastric venous ammonia concentration following subcutaneous histamine. The range of duplicate estimations of ammonia concentration is indicated

rise in arterial ammonia concentration 30–60 min after histamine in those cirrhotic patients with a previous history of hepatic coma or pre-coma, but not in cirrhotic patients without such a history. He suggested that the origin of this rise might possibly be related to gastric secretion. A further attempt has therefore been made to determine whether ammonia is released into the venous blood leaving the stomach during, or after, histamine stimulated acid secretion in dogs.

At laparotomy under pentobarbitone anæsthesia in eight mongrel dogs, a cannula was inserted into the splenic vein distal to the entry of the gastric veins, and splenectomy was performed. A fine nylon snare was passed around the splenic vein proximal to the entry of the left gastric vein, so that the venous drainage from the stomach could be obstructed temporarily at will while blood samples were taken[9]. A Thomas cannula was inserted into the stomach for collection of gastric juice. Blood ammonia was measured by a modification of Seligson's method. Gastric juice was titrated using Topfer's solution.

24–48 h later, control specimens of gastric secretion and gastric venous blood were taken, and 0·04 mg/kg histamine was injected subcutaneously. Gastric acid secretion and gastric venous *p*H and ammonia concentration were then monitored for 1·5–2 h.

In nine experiments on eight dogs we observed no increase in the ammonia-levels in gastric venous blood during the first 75 min after histamine (the period of gastric acid secretion). There was, however, a rise in the venous *p*H during this period.

75–150 min after histamine (the period following gastric acid secretion), we found a definite increase in the ammonia concentration of the gastric venous blood in one out of six experiments. Fig. 1 is a typical example of the findings in five of these animals. Fig. 2 shows details of the experiment in which an increase in the ammonia concentration was observed.

With this exception, therefore, we have been unable to demonstrate a rise in the ammonia concentration of gastric venous blood during, or after, histamine induced acid secretion. The rise in *p*H of the venous blood samples during acid secretion suggests that these consisted mainly of gastric venous effluent.

Iontophoretic Application of Gamma-Aminobutyric Acid on Crayfish Muscle

It has been observed that γ-aminobutyric acid (GABA) mimics the action of inhibitory transmitter in several crustacean muscles[1–5]. In these investigations the action of GABA was investigated by perfusing the preparation with solutions containing the drug, and iontophoretic micro-application of GABA to these preparations was not performed. The latter has advantages over the perfusion experiment in providing localized application of the drug and more precise control of its duration.

In the present experiment, single- or double-barrelled microcapillaries were loaded with 1 M GABA (*p*H adjusted to about 4 by hydrochloric acid) or with 1 M L-glutamate (*p*H 8). Under these conditions GABA is cation and L-glutamate is anion. Thus GABA was injected by cathodic (outward through the capillary) and L-glutamate by anodic current. The abductor muscle of the dactyl in the 1st or 2nd walking leg of *Cambarus clarkii* was used. The potential changes were recorded intracellularly with a capillary filled with 3 M potassium chloride and the membrane potential was changed by the current through a 3 M potassium citrate-filled microcapillary.

One barrel of a double-barrelled capillary was filled with GABA and the other with L-glutamate. Thus GABA and L-glutamate could be applied to the same spot. The capillary was moved along the surface of a muscle fibre while passing a strong cathodic current through a GABA-loaded barrel. Several spots were found on a muscle fibre where GABA produced a potential change, usually in a depolarizing direction at resting potential. Although more detailed investigations were undertaken with smaller injection currents, both rising and falling phases of the GABA-induced potential were found to be several times slower than those of the glutamate-induced depolarization[6]. Fig. 1 shows an example of the GABA-induced depolarization. The GABA-induced potential was obtained from a rather broad area, compared with that for the glutamate potential, and it was rather difficult to locate the GABA-sensitive spot critically. This is probably due to the rather large dose of GABA required to obtain an appreciable potential change and to its slow time course.

When the membrane potential was altered by polarizing current through a current electrode inserted in the same fibre, the GABA-induced depolarization reversed its sign at about −60 mV (Fig. 2). On the other hand, the glutamate potential had its reversal potential near zero membrane potential. In most cases the GABA-sensitive area overlapped with the glutamate-sensitive spot. How-

ever, at some spots the injection of GABA produced a potential change, but there was no response to the injection of L-glutamate and vice versa. Prolonged application of GABA produced a maintained potential change, in contrast to the glutamate potential which showed marked desensitization. It was shown that L-glutamate mimics the excitatory transmitter[6]. Thus, an interaction between GABA and L-glutamate might be expected, as is observed between the inhibitory and the excitatory transmitters. During and after conditioning doses of GABA, injection of L-glutamate produced less depolarization than when unconditioned.

We thank Prof. C. C. Hunt for his advice.

HÆMATOLOGY

Interaction of Glutathione and Epinephrine within the Human Red Blood Cell

REACTION of the sulphydryl group of glutathione with oxidation products of epinephrine, norepinephrine and β-3,4-dihydroxyphenyl-l-alanine *in vitro*[1-4] suggested a search for similar reactions involving the glutathione in intact red cells. The importance of such chemical behaviour arose from the fact that the fate of epinephrine and norepinephrine during the relatively brief period of their physiological action remained unknown[5]. During incubation of freshly drawn human blood with a catecholamine in the work recorded here, the total sulphydryl group of the glutathione within the red cells rapidly decreased. This observation suggested an interrelationship between the catecholamines and glutathione *in vivo*.

Human blood was obtained in random fashion from 45 healthy male and female volunteers aged 22–42 years, with use of aqueous heparin sodium obtained from the Riker Co. of Los Angeles, California, in a concentration of 5,000 units per ml. The bitartrate forms of the catecholamines were supplied by the Winthrop Co. of New York. Separate solutions containing 10 mg of epinephrine or norepinephrine or 8 mg of ascorbic acid per ml. of water were formed immediately before use. All chemicals were of reagent grade. Trichloroacetic acid and sodium hydroxide were kept in 5 per cent and 5 N solutions, respectively. After solution of 46·6 g of the tetrasodium salt of (ethylenedinitrilo)-tetraacetic acid (EDTA), obtained from the Matheson Co., in 800 ml. of water, 5 ml. of glacial acetic acid were added to adjust the *p*H to 7·5 and the volume was adjusted to 1 l. with water to form a 0·11 M solution of EDTA. A 0·0308 per cent solution of *bis* (*p*-nitrophenyl) disulphide (Eastman Kodak Co.) in acetone was formed (PNPD).

At zero time, the indicated amount of epinephrine in 0·1 ml. of water was added to 1 ml. of freshly drawn blood in a number of test-tubes. Each test-tube was incubated for the designated period of time in a water bath maintained at 37° C without evidence of hæmolysis. Then, for deproteinization, 9 ml. of trichloroacetic acid were added. Ten minutes later, the solution was filtered through Whatman No. 1 filter paper. To 1 ml. of filtrate was added a solution containing 4 ml. of EDTA, 4 ml. of acetone and 0·5 ml. of PNPD, in compliance with the method of Ellman[6] for measurement of sulphydryl groups. The absorbancy of the yellow colour was measured within 1 min thereafter at 412 mμ in a Beckman *DU* spectrophotometer, with water as the blank.

The decrease in the blood non-protein sulphydryl group which resulted from the presence of epinephrine in two different blood specimens is shown in Fig. 1. Essentially similar results were obtained in every case. Duplicate specimens in 15 experiments yielded results within 9 per cent of each other during all the experimental steps. The absorbancy of the residual sulphydryl group decreased rapidly within the first 5 min and reached an essentially stable value by 15 min. In the specimens tested, the initial absorbancy of the sulphydryl group varied, without apparent pattern, between 108 and 165, while the final levels for 1 mg of epinephrine ranged between 60 and 75 per cent of the initial levels. Increase in epinephrine up to 300 μg resulted in a corresponding decrease in the plateau level of the —SH group, while increase above 500 μg had little additional effect. The absence of bitartrate in epinephrine U.S.P. did not affect the results. Such easily oxidizable substances as l-norepinephrine bitartrate, isoproterenol hydrochloride (Winthrop Co.) and l-dihydroxyphenylalanine yielded essentially the same results as l-epinephrine bitartrate. D-Amphetamine sulphate (Smith, Kline and French), l-phenylephrine hydrochloride (Winthrop Co.) and methoxamine hydrochloride (Burroughs Wellcome) were ineffective. Use of

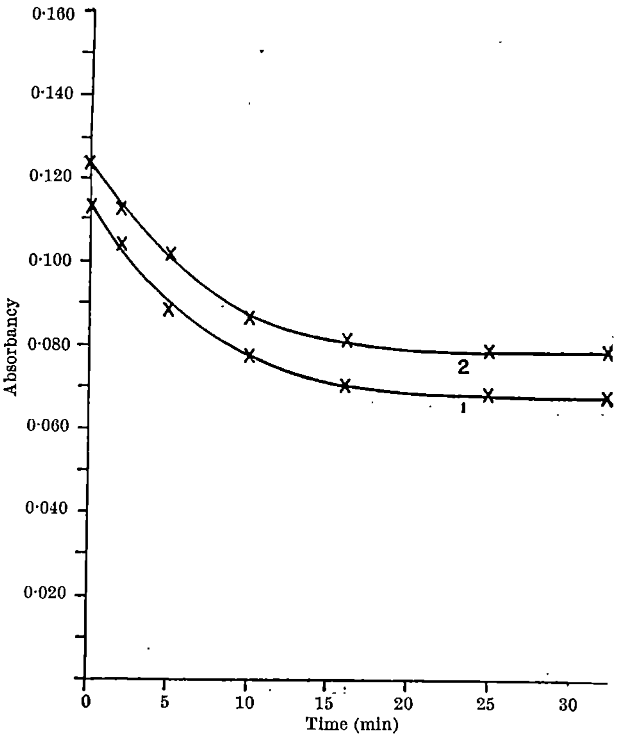

Fig. 1. Absorbancy as a function of time for the sulphydryl group remaining in 0·1 ml. of human blood on incubation of 1 ml. of blood at 37° C with 1 mg of epinephrine

EDTA as an anticoagulant yielded the same results as heparin. When 20 μg of glutathione in either 1 ml. of trichloroacetic acid or 1 ml. of water was added to Ellman's reagent, an average net absorbancy reading of 99, with a standard deviation of 7, was obtained in six determinations, the absorbancy of the PNPD blank without glutathione being six. During 30 min of incubation at 37° C in the absence of epinephrine, the non-protein sulphydryl group of blood did not change. Plasma did not effect the disappearance of the sulphydryl group significantly. Indeed, the net absorbancy of the —SH group in 1 ml. of the trichloroacetic acid filtrate formed from 1 ml. of plasma was only six. Furthermore, in contrast to the behaviour in blood, half of 200 μg of glutathione added to 1 ml. of plasma disappeared in 20 min, and 1 mg of epinephrine inhibited the decrease appreciably.

In investigations concerning the mechanism of the glutathione reaction, the epinephrine was added not to blood but rather to 1 ml. of blood trichloroacetic acid filtrate the *p*H of which had been adjusted to 7·5 by addition of 0·3 ml. of a 1·1 M EDTA solution. The results were essentially the same as in Fig. 1. Epinephrine did not cause disappearance of the —SH group below *p*H 5·2 within 30 min, while at *p*H 5·8 the disappearance was the same as at *p*H 7·5. The pink colour and the increased absorbancy at 480 mμ produced by as little as 4 μg of adrenochrome failed to appear as the —SH group decreased. Ascorbic acid had a marked effect on the disappearance of the —SH group in blood and filtrate. Addition of 3 mg of ascorbic acid to 1 ml. of blood immediately before 1 mg of epinephrine prevented disappearance of the —SH group for 30 min. One mg of ascorbic acid prevented the disappearance for 15 min; but nearly the full decrease in the —SH group occurred after 15–30 min. Similar results were obtained in the filtrate.

The non-protein sulphydryl group of the red cell is largely glutathione[7]. The recovery of glutathione added to blood was nearly 100 per cent in the Ellman technique, while added cysteine and ergothionine were not at all recovered[7]. Since the sulphydryl group of blood is present almost solely within the red cell, the progressive decrease in its concentration during incubation with epinephrine must have resulted from intracellular reactions. Only a small portion of the added epinephrine actually affected the sulphydryl group. Use of relatively large amounts of epinephrine was necessary to permit reasonably large changes in the absorbancy produced from the sulphydryl group. Sensitive methods, such as those dependent on radioactivity, should enable the results of the present investigation to be extended without difficulty to physiologically significant levels of epinephrine.

The inhibitory effect of ascorbic acid suggested that the disappearance of the —SH group involved oxidation of the epinephrine. Decrease in the —SH group on incubation of the protein-free filtrate with epinephrine indicated that the oxidizing agent was not a protein. It required a *p*H higher than 5·8 for full effectiveness. Its action was rapid but inadequately strong to produce any adrenochrome from the large excess of epinephrine, in contrast to manganese dioxide. The disappearance of erythrocyte glutathione in the presence of epinephrine in the present investigation was compatible with similar behaviour in the intact living organism. These observations might equally be applicable to the cells of such organs as the liver and kidney, in agreement with the finding that repeated injection of epinephrine into rats over 4·5 h led to a decrease in the glutathione —SH group within these organs[8]. The mechanism of the sulphydryl disappearance, including its relationship to the formation of presently known metabolic products of the catecholamines, such as metanephrine and normetanephrine[5], remained to be determined.

Panagglutination of Erythrocytes coupled with Diazotized *p*-Nitroaniline

MODIFICATION of erythrocytes *in vitro* by various enzymatic or chemical treatments renders them agglutinable by normal sera from mature donors. This agglutination reaction is called 'panagglutination'[1,2]. In the course of our investigation on the specific reaction of azohapten-erythrocytes with antisera against azohaptens[3], we observed that after coupling erythrocytes with diazotized *p*-nitroaniline (PNA), they were agglutinated by normal rabbit serum absorbed with untreated erythrocytes[3]. This communication deals with the finding of a similar phenomenon with human serum.

PNA-erythrocytes were prepared by adding 0·5 ml. of 0·005 M *p*-nitrobenzenediazonium chloride to a suspension of 0·05 ml. three-times washed packed human erythrocytes in 4·5 ml. phosphate buffer (0·15 M, *p*H 7·3) with immediate mixing. After standing for 15 min at room temperature, the coupled cells were washed twice with 10 ml. physiological saline, containing 1 per cent decomplemented rabbit serum absorbed with untreated human red cells, or 0·06 per cent human serum albumin, and then resuspended in 2·5 ml. of the same solution. To obtain consistent results, the erythrocytes used for coupling should be freshly drawn, and tested within 0·5–1 h after coupling. Normal and pathological human sera and plasma were obtained by venipuncture and used immediately, or stored at $-25°$ C. The sera used were either blood group compatible, or absorbed with a sample of the same cells which were afterwards coupled with PNA. Titration was performed on a glass plate as already described[3]. Controls with untreated erythrocytes, as well as controls of the coupled cells with saline only, were always included. Serum titres are expressed as the reciprocal of the highest dilution giving agglutination.

The results obtained with 235 human sera are summarized in Table 1. From the pattern of agglutination observed, it appears that the titre is raised in patients with hepatitis and anæmia as compared with sera from healthy donors. The titre is also raised in pregnant women. It is lowered, on the other hand, in patients with leukæmia. However, the number of sera is too limited to allow any definite conclusions. Inhibition tests with PNA-tyrosin and absorptions with insoluble PNA-γ-globulin as described in ref. 3 were performed and induced no appreciable reduction of the agglutination titres. This indicates that an agglutinin with a specificity directed against the hapten PNA is not involved in this reaction. Highly active $H(O)$-substance also failed to show an inhibitory effect. The agglutinating factor could be absorbed from the sera with PNA-erythrocytes, but not with untreated erythrocytes. The activity of this factor was not changed by heating the serum to 56° for 30 min; it was significantly reduced after 30 min heating at 62°, and completely destroyed after 30 min at 65°. All the agglutinating activity could be precipitated by 45 per cent saturation of the serum with ammonium sulphate[4]. The precipitate was dissolved and made up to the original volume in physiological saline. Tested against PNA-erythrocytes, it gave the same titre as the serum from which it was prepared. By paper electrophoresis, it was shown to contain 70–80 per cent β- and γ-globulins, small amounts of α_2- and traces of α_1-globulin.

Table 1

Serum donors	No. of sera tested	No. of sera having a titre of: <1	1	2	4	8	16	32	64	128	>128

† Lymphocytic and myelocytic leukæmia, lymphogranulomatosis.

‡ Including polyarthritis, rheumatic fever, nephritis, nephrosis, liver cirrhosis and jaundice.

Rabbit and guinea-pig sera and erythrocytes, obtained by carotic bleeding, were also tested. The animal sera were always carefully absorbed with an untreated sample of the cells which were afterwards used for coupling with PNA. After absorption, these sera did not agglutinate the untreated cell control, but did agglutinate human PNA-erythrocytes. The titres were somewhat lower than for human sera (cf. Table 1).

All tested human red blood cells could be rendered panagglutinable without respect to their blood group. When erythrocytes from various donors were tested against the same serum, the titres were identical. The same titre was also obtained when the serum donor's own red cells were used. The PNA-treated erythrocytes are brown in colour and show a high tendency to hæmolyse. When other diazotized amines were used for coupling, as, for example, p-sulphanilic acid or p-aminobenzoic acid, panagglutination titres were significantly lower or absent. However, in these cases, the treated cells did not show such an increased tendency to hæmolysis. Rabbit and guinea-pig PNA-erythrocytes usually gave negative results when tested against human, rabbit and guinea-pig sera; only in a few cases were low titres obtained. All tested human and animal PNA-erythrocytes gave a high titre with a specific rabbit anti-PNA serum.

Since no serological relation to the coupling agent, to $H(O)$-substance, or to blood group agglutinogens could be demonstrated, the agglutination of PNA-erythrocytes appears to be a typical panagglutination. As such, it would be comparable with the agglutination of erythrocytes treated with the enzymes neuraminidase[5] or trypsin[6], which is thought to be due to an uncovering of pre-existing receptors on the red cell membrane, or with the agglutination of erythrocytes treated with the oxidizing agent periodate[7].

We thank Prof. Georg F. Springer for a gift of $H(O)$-substance.

Appearance of Slow α_2-Globulin during the Inflammatory Response of the Rat

Slow α_2-globulin is a protein of large molecular weight which becomes demonstrable by vertical starch-gel electrophoresis in the serum of the rat under a variety of conditions, mostly related to growth. It cannot be demonstrated by this means in healthy, non-pregnant adult animals but has been demonstrated in connexion with normal growth[1–3], neoplastic growth[1,2,4,5], regenerative or compensatory growth[6,7], pregnancy[1,2], tight abdominal bandaging[4], Caesarean section with retention of a single placenta[1], implantation of homologous minced kidney tissue[7], unilateral kidney ligation[7] and in certain states resembling mild infectious diseases[1,6]. The appearance of slow α_2-globulin in the last few of these conditions, together with the observation that it becomes sporadically demonstrable after limb amputation or sham surgery[7], especially in the presence of obvious wound infection, led to the hypothesis that, in addition to growth, the presence of an infection and/or an inflammatory condition can elicit the appearance of slow α_2-globulin in the serum of the rat.

In order to test this hypothesis, rats were subjected to various treatments designed to produce a localized or generalized inflammatory state. Sera were obtained as previously described[2] from Sprague–Dawley rats, of either sex, raised in our laboratory or purchased from the Holtzman Co., Madison, Wisconsin. Little difference in the responsiveness of the two sexes was noted. Vertical starch-gel electrophoresis was performed by the method of Smithies[8], with minor modifications[2]. Lipopolysaccharides (endotoxins) of *Salmonella abortus equi*, *S. typhosa* and *Escherichia coli*, produced by the Westphal method[9] and obtained from Difco Laboratories, Detroit, Michigan, were administered intraperitoneally in the doses indicated in Table 1 as a 1 per cent (w/v) suspension in sterile 0·9 per cent saline. Complete and incomplete Freund's adjuvants (Difco Laboratories) were administered intraperitoneally without dilution in the doses shown in Table 1. For the evocation of a localized inflammation, croton oil (Frank W. Kerr Chemical Co., Detroit, Michigan) was administered intradermally into one or two abdominal sites as a 75 per cent (v/v) solution in peanut oil[10]. Controls

Table 1. APPEARANCE OF SLOW α_2-GLOBULIN AFTER ADMINISTRATION OF VARIOUS SUBSTANCES

Substance administered	Vehicle	Route*	Dose	Presence†	No. of animals in each category at indicated No. of days after administration

consisted of untreated rats, rats injected intraperitoneally with either sterile 0·9 per cent saline or mineral oil or intradermally with peanut oil.

The results obtained are shown in Table 1. Slow α_2-globulin was demonstrable in every case two and four days after the administration of any of the three endotoxins tested. When the endotoxin of *S. abortus equi* was used, slow α_2-globulin first became demonstrable about 12 h after injection, but was no longer demonstrable in the majority of rats nine days after administration. In none of the control animals injected with sterile saline could slow α_2-globulin be demonstrated. The results obtained here with respect to the endotoxin of *E. coli* are in general agreement with those of Lawford and White[11] which came to our attention during the course of the work.

Since complete Freund's adjuvant contains killed and dried *Mycobacterium butyricum* and is said to modify the cellular reaction about its site of deposition, we investigated the possibility that its administration might provoke demonstrable levels of slow α_2-globulin. Such was the case at both dose-levels tested. However, incomplete Freund's adjuvant, lacking the *M. butyricum* when injected at the rate of 2 ml. per rat, also provokes this response. At the lower dose-level of 0·35 ml. per rat, the incomplete adjuvant, contrary to the action of the complete adjuvant, stimulates only an occasional and weak response. Control injections of mineral oil at either levels proved uniformly negative. The generally superior ability of complete adjuvant in enhancing the immune response as compared to incomplete adjuvant may perhaps be related to the difference in the ability of these two mixtures to provoke demonstrable levels of slow α_2-globulin.

Since the foregoing seems to show that generalized inflammatory responses lead to demonstrable levels of slow α_2-globulin, the question arose as to whether or not a localized inflammation would also do so. The administration of croton oil on to or into the skin provokes a localized inflammatory reaction[10,12]. As shown in Table 1, the intradermal injection into one or two sites of a total of 0·3 ml. of croton oil as a 75 per cent solution in peanut oil evokes demonstrable levels of slow α_2-globulin in all cases tested. Control rats injected with corresponding quantities of peanut oil remained uniformly negative.

The administration of some or all of the foregoing substances may provoke some slight tissue synthesis. There are, then, at least two proximate mechanisms here which might lead to the production of demonstrable quantities of slow α_2-globulin: small amounts of tissue synthesis or a component of the inflammatory response. The former is the less likely as generally no demonstrable slow α_2-globulin level appears during the healing processes following such procedures as limb amputation[7] and laparotomy[6,7] in the absence of wound infection. The alternative conclusion, that the appearance of demonstrable concentrations of slow α_2-globulin is, in these experiments, related to a component of the inflammatory response, is strengthened by the appearance of slow α_2-globulin in conditions of frank tissue degeneration as after the intraperitoneal implantation of minced homologous kidney tissue or after ligation of the blood vessels of one kidney[7].

It may be concluded, then, that slow α_2-globulin becomes demonstrable, by starch-gel electrophoresis, in the serum of the rat, during a localized or generalized inflammatory response, as well as during tissue synthesis.

PATHOLOGY

Effect on Leukæmic Cells of Ribonucleic Acid extracted from Calf's Spleen

IT has been demonstrated that modifications may be produced in the metabolism of certain experimental tumours by cultivating them with RNA.

Cells of ascites tumour of mice have been incubated with RNA from a normal liver. An impressive reduction was noted in the capacity of these cells to reproduce the original tumour when grafted on to the tissue of other animals. This loss of malignity was due not to the death or diminished vitality of the cells, but to an actual transformation induced by the RNA with which they had been incubated. This was clearly demonstrated by the fact that the cells had acquired characteristics typical of hepatic cells, such, for example, as the ability to produce albumin, tryptophan-pyrrolase and glucose-6-phosphatase[1,2].

This phenomenon was observed not only in the case of Nelson's ascites tumour, but also in other cases of neoplasia (Ehrlich's ascites tumour, Novikoff's rat's hepatoma, etc.). That the transformation induced by RNA is permanent is seen by the fact that not even after a considerable lapse of time do the treated cells regain their original characteristics of neoplastic structures. That the RNA with which they were cultivated provides the essential factor in the transformation of the tumorous cells is proved by the fact that after treating with RNase the effect of RNA from the liver on the tumorous cells ceases completely[2].

On the basis of these observations, we have been, for some time past, carrying out a series of experiments to determine the effect of RNA extracted from various organs on human neoplasias cultivated *in vitro*. The first obstacle encountered in this work was due to the fact that human tumorous tissue is little adapted to cultivation *in vitro*, being constituted of cells presenting, in the majority of cases, phenomena of initial necrosis. Secondly, in the case of solid tumours it is exceedingly difficult to produce a culture of cells similar to each other from a morphological point of view; in consequence, the evaluation of eventual structural or metabolic changes becomes problematic.

Because of these facts I had recourse for the purpose of these experiments to the bone marrow of subjects affected with acute leukæmia or histiocytic medullary reticulosis. In these cases it often happens that the cells of bone marrow are for the most part of the identical, reticular type, which fact notably facilitates the evaluation of eventual morphological or metabolic changes.

Cultivation of leukæmic cells of bone marrow with RNA extracted from the spleen of calf embryo led to the formation of specific structures. At the start of the culture phase, the electron-microscopic investigations strongly suggested the scarcity of endoplasmic reticulum and the abundance of unattached granules lying free in the cytoplasm. In the case of cells in the culture containing RNA, a change in their morphological characteristics was noted in a fairly good percentage (40–48 per cent) after the lapse of 10–72 h (increase of ergastroplasm; parallel orientation of the membrane system; small dense particles studded on the outer surface of the membrane)[3].

The results recorded here refer to the metabolic changes observed in the cells obtained from the bone marrow of 5 subjects affected with acute leukæmia.

The medullary tissue, obtained by means of biopsy, was immediately mixed with sterile Tyrode's solution containing minute quantities of heparin. After having been placed in a refrigerator at a temperature of +2° C and left for 30 min, the particles of medullary matter adhering to the surface of the liquid were removed and immersed in a matrass containing the incubation mixture[4] to be used for the culture. By means of gentle agitation the medullary matter was dissolved in the liquid. The number of cells present in every 1 mm^3 having been counted, a quantity of the incubation mixture sufficient to raise the cellular concentration to 6,500 elements/mm^3 was added. One aliquot of this cellular suspension was immediately used as the control for starting respiratory activity[5]. One aliquot was transferred to a metabolic shaker (control). To the other part was added RNA (2 mg/ml.) extracted from the spleen of calf embryo by a technique already described by other research workers[6]; then the suspension was transferred to a metabolic shaker. Incubation was carried out under sterile conditions for 24 h at 37° C. Then the respiratory activity of cells was examined.

In the case of the cells in the culture containing RNA, a change in their metabolic characteristics was noted; in fact the oxygen consumption of RNA-treated cells is significantly increased (Table 1). The cells in the control culture, where no RNA was present, however, retained the same metabolic characteristics as at the beginning of the experiment.

These results demonstrate that cells of acute leukæmia are affected by the presence in the incubation mixture of RNA extracted from the spleen of calf embryo, an organ well known for its high proportion of cells having hæmopoietic properties. It is important to remember that the oxygen consumption of leukæmic cells is considerably less than that of the normal homologous cells. The increase of oxygen consumption in leukæmic cells indicates that information transfer within hæmopoietic cells can be effected, possibly by incorporating an RNA template containing 'normal' information which competes with pre-existing 'pathological' information systems.

Table 1. OXYGEN CONSUMPTION* OF BONE MARROW CELLS OF 5 SUBJECTS AFFECTED WITH ACUTE LEUKÆMIA BEFORE AND AFTER INCUBATION WITH RNA

Relationship of Adrenocortical Insufficiency to Spontaneous Regression in Mammary Tumours induced in Rats by Oral Administration of Dimethylbenzanthracene

IT has been shown that many of the tumours induced in rats by the oral administration of 9,10-dimethyl-1,2-benzanthracene (DMBA) stop growing and some undergo spontaneous regression[1,2]. It has also been shown that DMBA produces massive adrenocortical necrosis when given in doses which would ultimately give rise to tumours[3]. It appeared possible that spontaneous regression might be due to adrenocortical insufficiency which permitted the development of an immunological mechanism. This communication reports experiments designed to test this hypothesis.

Two hundred and forty rats, descended from stock imported from Sprague–Dawley of Madison, Wisconsin, and commercially available in Britain, were used. They were obtained at 40 days of age and were divided into two groups by a formal randomization process. 50 mg of DMBA dissolved in 2 ml. of corn oil were given to all rats on the 50th day of life by intragastric tube. Starting on the day the DMBA was given, Group 2 was given 3 mg of cortisone acetate daily for 1 week, 2 mg of cortisone acetate daily for a second week and 1 mg of cortisone acetate daily for a third week, after which cortisone acetate treatment was terminated. This dose of cortisone acetate is believed to be adequate to replace the output of the damaged adrenal cortex during the 3-week period of its regeneration[4].

Table 1

Days after DMBA		Rats with tumours	No. of tumours Growing	Static	Regressing	Total	P
100	DMBA	28/34	11	23	4	38	n.s.
	DMBA + cortisone	18/26	10	16	3	29	
150	DMBA	30/34	13	35	10	58	n.s.
	DMBA + cortisone	20/26	14	31	7	52	
200	DMBA	31/34	17	45	13	75	n.s.
	DMBA + cortisone	20/26	15	31	10	56	

Table 2

	Mean induction period (days)	P
DMBA	71·186 ± 2·760	n.s.
DMBA + cortisone	79·696 ± 4·596	

Twenty-three rats in each group were killed 3 days after giving DMBA. The adrenals were examined histologically for evidence of massive necrosis. Rats were examined twice weekly for tumour production from the 4th week onwards and when tumours had been detected these were measured with calipers and their mean diameter recorded.

Depending on their ensuing behaviour, tumours were allocated to one of the three groups, growing, static or spontaneously regressing[1].

Massive adrenal necrosis was found in 21 out of 23 rats examined in Group 1 and in 23 out of 23 rats examined in Group 2. The numbers of growing, static and spontaneously regressing tumours 100, 150 and 200 days after DMBA are given in Table 1. The differences between the incidence of the three tumour types are not significant at these times. It is possible that the induction period of tumours might be altered by the effect of adrenocortical insufficiency and we have given the induction period of all tumours in Table 2. No significant difference exists, however, between these two groups.

It is clear that the replacement dose of cortisone acetate has not in any way influenced either the induction period of tumours or the occurrence of tumours which ultimately fail to grow or regress.

Renal Immunofluorescence in *NZB/NZW* Mice

INVESTIGATIONS carried out by Helyer and Howie on a hybrid strain of mice derived by crossing the *NZB/BL* and *NZW* strains show that these animals died of renal failure within 8–10 months[1]. The renal lesions in these animals closely resembled those seen in human lupus nephritis. Using conventional microscopical techniques marked glomerular changes, including fibrinoid necrosis, thickening of the basement membrane and wire-loop formation were demonstrated.

The development of the renal lesions in these animals has been examined by immunofluorescent techniques. Groups of mice of both sexes were killed at monthly intervals and similar groups of *CBA/T6* mice were used as normal controls.

A concentrated globulin fraction of a rabbit anti-mouse serum was obtained by three precipitations with a half-saturated ammonium sulphate solution[2]. An electrophoretic pattern of this fraction revealed it to comprise of mostly γ-globulin and some β-globulin. The antiserum was conjugated with fluorescein isothiocyanate[3,4] and purified by dialysis and extraction with charcoal[5]. Non-specific staining materials were absorbed by mouse liver powder (Baltimore Biological Laboratory) prior to use[2,6].

Unfixed kidney tissues, which were obtained as soon as possible after killing the mice, were rapidly quenched in liquid air and 4–5μ sections were cut in a cryostat. The sections were transferred to a glass slide, washed in phosphate-buffered saline and covered with the F.I.T.C. conjugate together with a bovine albumin–rhodamine counter stain (Baltimore Biological Laboratory)[7]. Staining was allowed to proceed for 30 min and the sections mounted in buffered glycerol. Tests proving the specificity of the conjugated serum have been carried out[4,8].

Up to the age of about 6 months the glomeruli appear to be normal and are uniform in size. Although many fluoresce the intensity is notably very pale, at times ghostly, and is markedly patchy generally only involving portions of the tuft. Sharply localized thin areas of brighter fluorescence are evident in a few glomeruli. The tubular basement membranes show as fine structures, with diffuse and moderately bright fluorescence. A similar form and degree of fluorescence has been noted in the control animals examined up to the age of 12 months; this may be explained by the investigations of Tan and Kaplan[9], who showed that in the normal mouse the basement membranes of the renal parenchyma and other organs fluoresced and that the component associated with this staining was related to the β-globulin serum fraction.

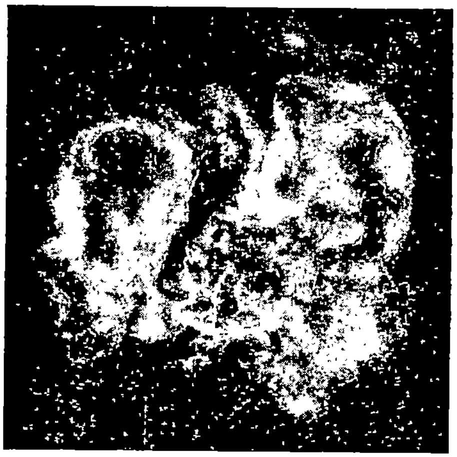

Fig. 1. Glomerulus showing thickened basement membrane and wire-loops. Marked granularity of fluorescence is evident (×420)

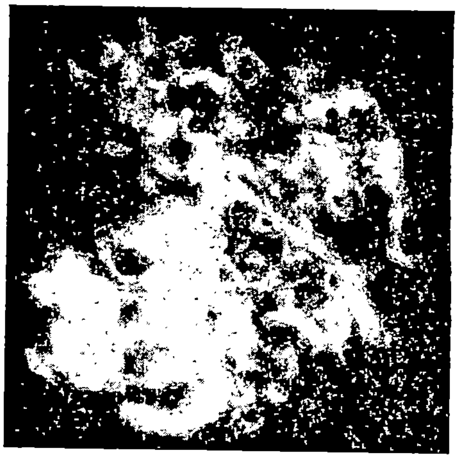

Fig. 2. Large focal lesion with dense and granular fluorescence in a glomerulus (×420)

Beyond the age of 6 months marked fluorescent changes become evident. The glomeruli are generally larger than those seen in the control animals and all fluoresce brilliantly. In all cases there is a progressive increase in thickness of the basement membrane as judged by the areas of fluorescence and, particularly in the older animals, this becomes greatly increased, often producing the appearance of wire-loops (Fig. 1). The fluorescence is irregular, patchy and, in many cases, strikingly granular. In addition occasional glomeruli present focal areas of dense, bright fluorescence involving the whole or part of a lobule (Fig. 2). An associated feature seen in some of the older animals is an increase in lobulation of the tufts. All these changes become evident sooner and more marked in the female animals.

In the tubules no cellular or basement membrane variations have been noted, but in some older animals the tubules are dilated and many are seen to contain faintly fluorescing granular material. There has been little, if any, alteration in the arteries and arterioles in mice examined up to the age of 12 months and no fluorescence has been seen, as yet, in the lymphoid aggregations that form such a striking feature in conventionally stained sections.

The close similarities seen in the renal lesions of human lupus nephritis and the *NZB/NZW* mice have already been indicated. Comparison of the fluorescent patterns seen in these cases as well as in other forms of human nephritis is possible. It is believed that such investigations would be of value in elucidating the nature of the lesions.

IMMUNOLOGY

Dissociation of Bacterial 0 Antigen from Rabbit Erythrocytes

IT has been shown[1] that rabbit erythrocytes modified *in vitro* with 0 antigens (endotoxins) of *Salmonella typhi* or *Escherichia coli* are rapidly destroyed when injected into rabbits previously immunized with the corresponding bacterial antigen. In contrast, modified erythrocytes administered to non-immune rabbits have a normal life span despite the fact that specific antibody appears within six days after injection of the modified red blood cells. Thus, it becomes important to ascertain whether bacterial antigens attached to erythrocytes *in vitro* remain bound to the red blood cells for their entire period of survival after they are re-introduced into the animal's circulation.

Erythrocyte survival was measured, using autologous red blood cells tagged with radioactive sodium chromate (chromium-51); the half-life of chromium-51 for normal autologous rabbit erythrocytes ranged from 10·5 to 17 days[1]. Autologous rabbit erythrocytes modified with sodium hydroxide treated typhoid 0 antigen (6,000 μg/ml. of 50 per cent red cell suspension) had a half-life of chromium-51 of 10–13 days[1].

An experiment was designed to detect the presence of antigen-modified erythrocytes in the rabbit's circulation by means of direct differential agglutination[2]. With this technique erythrocytes modified with typhoid 0 antigen were readily detected when the proportion of modified to normal erythrocytes was as low as one part in 20 (5 per cent). Approximately 50–70 ml. blood was obtained from each of three rabbits the sera of which contained no detectable antibody against typhoid 0 modified erythrocytes. The red blood cells were modified with the typhoid 0 antigen[1] and were administered intravenously to the original donor animal. Blood samples were obtained from the marginal ear vein 15 min after the injection of modified cells and twice daily thereafter. The presence of modified erythrocytes in each sample was demonstrated by direct differential agglutination using potent typhoid 0 antiserum.

The results of these experiments (Table 1) show that agglutinable red blood cells were not detected 4–6 days after administration of modified erythrocytes. These observations suggest that the bacterial antigen is removed from the erythrocytes *in vivo*. Alternatively, it is conceivable that the agglutination of the modified erythrocytes *in vitro* was 'blocked' by the newly formed antibodies which appear as early as three days after administration of the modified red blood cells.

Table 1. Disappearance of agglutinable erythrocytes from the circulation of rabbits after injection of autologous erythrocytes modified with typhoid 0 antigen

Rabbit No.	Percentage of agglutinable erythrocytes			
	Day 0	Day 2	Day 4	Day 6
98	50	35	25	< 5
95	35	20	< 5	< 5
99	50	30	< 5	< 5

To resolve this problem, experiments utilizing endotoxin labelled with radioactive chromium were undertaken. Sodium-hydroxide-treated *E. coli* 0111 : *B*4 lipopolysaccharide (Difco Lot No. 132562) was labelled with chromic chloride (chromium-51) according to the method of Braude *et al.*[3]. Preliminary work with three rabbits disclosed that the life-spans of autologous erythrocytes modified with non-radioactive antigen (2,000 μg/ml. 50 per cent erythrocyte suspension) were within the normal range (half-life of chromium-51, 12, 14 and 15 days). Approximately 50 ml. blood was obtained from each of three rabbits the sera of which contained no detectable antibody against *E. coli* 0111 : *B*4. The erythrocytes were coated with the chromium-51-labelled antigen; modification of the red cells was confirmed serologically and by demonstrating uptake of radioactivity by erythrocytes. 96 per cent or more of the radioactivity in the final cell suspension was bound to erythrocytes. Autologous red cells were administered intravenously to each rabbit and blood samples were obtained 1/4, 1/2, 1, 2, 24 and 48 h after the injection. The samples were counted in a well-type scintillation detector for a period of time sufficient to ensure a counting error of less than 10 per cent. The results shown in Table 2 support the conclusion that bacterial antigen is removed from modified erythrocytes after they are re-introduced into the animal's circulation.

Table 2. Disappearance of radioactivity from circulation of rabbits after injection of autologous erythrocytes modified with chromium-51-labelled *E. coli* 0 antigen

Rabbit No.	Half-life of ^{51}Cr (min)	Percentage radioactivity remaining after 24 h
168	90	25
171	45	10
179	90	17

In view of these results it seemed advisable to re-examine *in vitro* the avidity of the binding of bacterial antigen to red blood cells[4,5]. Rabbit erythrocytes were modified with the chromium-51-labelled *E. coli* 0111 : *B*4 antigen; the concentration of radioactivity per ml. of packed red blood cells was measured before and after multiple washings with isotonic sodium chloride solution. The results shown in Table 3 demonstrate that radioactivity and presumably antigen is removed from erythrocytes by repeated washing. The observation that a 40 per cent loss of endotoxin from the erythrocytes does not alter agglutinability is not surprising because Luderitz *et al.*[6] demonstrated that one erythrocyte was able to bind approximately 100,000 molecules of an *E. coli* 0 antigen and yet only 5,000 molecules per erythrocyte were necessary for positive hæmagglutination.

Table 3. Effect of repeated washing on rabbit erythrocytes modified with chromium-51-labelled *E. coli* 0 antigen

No. of eight-vol. washings	Hæm-agglutination titre	Radioactivity c.p.m./ml. of packed erythrocytes	Cumulative loss of radioactivity (%)
0	1/800	8,576	0
6	1/800	7,705	12
12	1/800	6,333	28
18	1/800	5,195	40

In order to ascertain whether the loss of radioactivity was due to a disruption of the bond between erythrocyte and antigen, or to a loss of chromium-51 from the antigen itself, two further experiments were carried out. Chromium-51-labelled antigen was dialysed for a period of 6 h with a loss of only 2 per cent of the radioactivity into the dialysis bath. A 50 per cent suspension of erythrocytes modified with chromium-51-labelled *E. coli* antigen was dialysed for 6 h in a bath of isotonic sodium chloride solution. Despite the fact that many of the red cells were hæmolysed, less than 2 per cent of the radioactivity was lost in the dialysis bath. Therefore, it appears that the bond between the chromium-51 and the antigen is stable even after antigen is attached to erythrocytes.

In conclusion, these observations suggest that 0 antigen, or a portion of it, is removed from modified erythrocytes by repeated washing and by re-introduction of the modified red blood cells into the rabbit's circulation.

I thank Dr. Erwin Neter for his advice and Dr. Victor Bokkenheuser who kindly supplied the typhoid 0 antigen for these investigations.

Specific Inhibition of Anti-*D* by Human Urinary Mucoprotein

Sialic acid and polymers containing sialic acid[1-3] have been shown to specifically inhibit agglutination of *Rho*(*D*) red blood cells by specific antiserum. Urinary mucoprotein, which consists of 9·1 per cent sialic acid[4] in terms of total mucoprotein, was therefore considered as a possible inhibitor of anti-Rh. The other sugars which make up the prosthetic group of this molecule have been shown not to block specifically Rh agglutination[5].

Two separate preparations of urinary mucoprotein[6], isolated from pooled human urine and designated as *A* and *B*, respectively, were tested for their ability to inhibit the agglutination of trypsinized *Rho*(*D*) red cells by specific antiserum. The results are given in Table 1.

Table 1. Inhibition of Anti-Rh by Urinary Mucoprotein

Urinary mucoprotein preparation	Anti-Rh control	μg of mucoprotein required for inhibition
A	3+	400
B	3+	450

Optimal inhibition was obtained when red cells were added immediately following the mixing of mucoprotein and anti-Rh. Anti-C, anti-E and anti-c were not inhibited by the mucoprotein. Also, a maximal agglutinating dose of anti-D(4+) was not inhibited by the concentrations of the mucoproteins used (400 μg for *A*, 2,000 μg for *B*). 200 μg of preparation *A* inhibited anti-D after previous treatment with a 1 per cent solution of trypsin, a phenomenon somewhat analogous to that of the 'exposure' of Rh receptors on red cells treated with trypsin.

This report supports previous work suggesting an antigenic relationship between sialic acid and the D antigen.

BIOLOGY

Probable Fertile Region of *Asteroxylon mackiei* K. and L.

Asteroxylon mackiei was first described from the Rhynie Chert by Kidston and Lang[1], but the nature of its reproductive region has remained uncertain, since the peculiar leafless axes and small pear-shaped sporangia, which they provisionally assigned to the plant, have never been found connected to its leafy stems.

During a survey of loose block material containing abundant remains of *Asteroxylon mackiei* and the other organs referred to above, a few small shoots have been discovered bearing sporangia of a quite different type interspersed with veinless 'leaves'. It is the purpose of this communication to give a preliminary description of these and to suggest that they, rather than the naked sporangiophoric axes, may represent the true fertile region of the plant.

The rather large sporangia (up to 7 mm in width when empty) are tangentially flattened and are borne laterally and independently in the shoots between the leaves. Reconstructions based on serial peel sections have shown them to be somewhat reniform. Although most of the sporangia are empty, a few have been found containing spores which are about 50μ in diameter, and it is evident that these were shed through an extended marginal slit.

Each sporangium is borne on a short vasculated pedicel which expands distally into a pad of tissue over which the spore-sac extends. In median radial section no clear distinction can be made between these two regions and the length of the pedicel thus tends to be exaggerated.

Fig. 1 shows the appearance of one of the shoots in longitudinal section bearing on the right two empty sporangia, the lower of which is cut in the median plane. Parts of at least three other sporangia are present on the left side of the section, but the distal regions of the upper

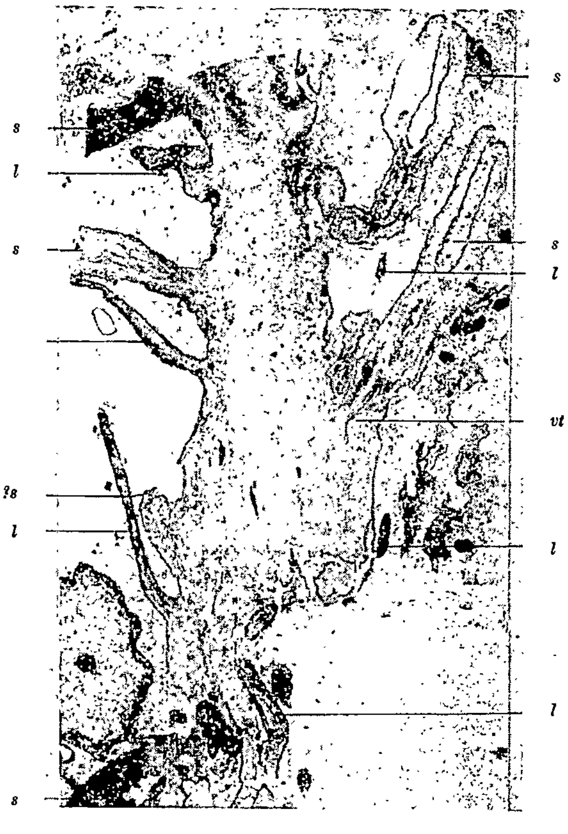

Fig. 1. Longitudinal section through leafy fertile shoot (×*c*. 8). *s*, sporangium; *l*, leaf; *vt*, vascular supply to sporangium

two have been severed and displaced by a fault in the block and lie outside the field of view.

A fortunate series of vertical sections through a shoot tip has indicated that the sporangia reached maturity only a short distance behind the apex. In this region the vascular tissue seems to consist largely of sporangial traces. Older shoot fragments bearing empty or withered sporangia have weakly developed actinosteles the xylem of which is composed of angular, fusiform tracheids with narrow wall thickenings, closely resembling those of *A. mackiei*. No clear evidence of leaf traces has been found, although this may be due to the very indifferent preservation of the material.

The provisional assignation of the leafless axes and small sporangia to *A. mackiei* by Kidston and Lang was based on evidence of close and constant association in the apparent absence of any alternative reproductive organs. Some support for this was later seen in the structure of the more completely preserved German species, *Asteroxylon elberfeldense*, Kräusel and Weyland[2], the leafy stems of which were clearly shown to terminate in leafless sporangium-bearing branches. It is difficult, however, to know how much weight should be attached to this indirect evidence which assumes a close natural relationship between the two plants. Although there are several unquestionable points of resemblance, there are likewise a number of well-marked differences the importance of which may require re-evaluation. Thus, while both leafy and leafless shoots of *A. elberfeldense* are circinately vernate, there is no suggestion of this in the case of *A. mackiei*. Furthermore, the tracheids of *A. elberfeldense* are scalariform or roundly pitted, while those of *A. mackiei* have narrow spiral thickenings; and whereas the stele of the larger stems of *A. elberfeldense* is medullated, no pith is present in *A. mackiei*. So far as the Rhynie species is concerned there are histological difficulties in the way of matching-up the leafy and leafless shoots. In addition to marked differences in tracheid size, those in the leafless axes have never been found to exhibit any traces of wall thickening or pitting although very many examples have been carefully examined (cf. Kidston and Lang). The tracheids of the leafy stems of *A. mackiei*, on the other hand, frequently show clearly recognizable wall thickenings even when preservation, in other respects, is extremely poor. While these differences do not preclude the possibility that the shoots are closely related parts of the same plant, they certainly lend no direct support to such an interpretation of their nature. Assuming, as seems likely, that either one or the other of the two kinds of fertile axis belongs to *Asteroxylon mackiei*, available evidence tends to favour rather strongly the leafy rather than the leafless type. Indeed, it can be said that, had it not been for the sporangia, the new fossils would have been passed over without hesitation as young shoots of that plant. While certainty regarding their nature is clearly impossible owing to the fragmentary condition of the remains, the probability that they represent fertile branches of *Asteroxylon mackiei* seems sufficiently high to justify provisionally assigning them to the plant in place of the leafless sporangiophoric axes. Consequent on this, the latter must be re-interpreted as reproductive portions of an incompletely known, but quite distinct, type of plant for which the name *Nothia aphylla* gen. et sp. nov is proposed.

In its habit and anatomy *A. mackiei* has been compared with *Lycopodium*, and Scott[3] ventured to suggest that "were it not for the peculiar axes associated with it, [it] might be regarded as an early representative, or at least a precursor of the lycopod series". While the new fertile shoots (if correctly assigned) do not establish the plant as a lycopod, they appreciably and perhaps significantly increase its resemblance to one.

A comparison can also be made, however, between the new sporangia and those of the leafless *Zosterophyllum* and it is possible to see in the leafy, fertile shoots a degree of structural complexity which is, in certain respects, intermediate between that of a bractless spike of reniform sporangia (as, for example, in *Zosterophyllum*) and a typical lycopod strobilus of sporophylls. But in the present state of our knowledge it would be facile to suppose that these represent a series of evolutionarily related forms.

Although the sporangia of *Zosterophyllum* are rather lycopod-like in their shape and manner of dehiscence (as Lang and Cookson[4] and Bower[5] have pointed out), any connexion between the Zosterophyllaceae and the Lycopsida, if it exists at all, may well be remote and indirect. Furthermore, while *A. mackiei* exhibits a number of morphological features which it would not be altogether surprising to find in a lycopod precursor—particularly if conceived in terms of the enation theory—the historical record of the group seriously conflicts with such an interpretation of the plant. It must, therefore, be rejected unless the view is taken that at least some of the more simply constructed early Devonian plants may have been relict types.

Thermophilic Fungi associated with Nigerian Oil Palm Produce

During the course of investigations into factors affecting the quality of palm kernels (that is, the kernels of the oil palm, *Elaeis guineensis* Jacq.) in Nigeria, it was observed that temperatures of the order of 60° C frequently developed within the stacks of undecorticated kernels that accumulated at oil mills[1]. It was further noted that fungal mycelia appeared to be growing profusely within these stacks.

Routine isolations were made from the interiors of a number of such stacks, using a palm oil/peptone/agar medium, incubated at 30° C—a temperature near the normal Nigerian ambient. These yielded predominantly *Rhizopus nigricans* Ehrenberg and occasionally other lipolytic fungi commonly associated with oleaginous material in Nigeria[2].

Thermophilic fungi are frequently found in self-heating plant materials[3,4]. In view of this, further isolations were made, using the same medium, but incubating the isolation plates at 50° C. Under these conditions, an entirely different spectrum of fungal species developed. From thirty-six samples examined, originating from oil mills in various parts of Eastern Nigeria, one or more of three fungi were consistently isolated. A *Thermomyces* species (I.M.I. 96473) was found to be present in every case, *Chaetomium thermophile* La Touche (I.M.I. 96472) was present in twenty-seven of the thirty-six samples, and an ascosporic *Penicillium* sp. (I.M.I. 96474), similar to *P. duponti* Griffon et Maublanc emend. Emerson, in only five: no other fungi developed from any sample, at this temperature.

C. thermophile was originally reported[5] in the United Kingdom, as occurring on straw compost, and as having an optimal growth temperature range of 40°–55° C. This species has also been isolated from coastal grassland soils in the United Kingdom[6]. *P. duponti sensu stricto* has previously been reported from retting guayule in California, when it had an optimal growth temperature range of 47°–50° C, and from fresh manure and wet hay in France[7]. The third organism appears to be a new *Thermomyces* species, distinct from any previously re-

Table 1

		Temperature (°C)	
	Optimum	Maximum	Minimum
Thermomyces sp.	42–47	60–61	31–35
C. thermophile	47–52	60–61	26–30
Penicillium sp.	43–52	58–59	31–35

ported thermophilic *Thermomyces* species. A full description of this species will be published elsewhere.

The temperature/growth relationships found for the Nigerian isolates are as given in Table 1.

All three organisms were found, by the use of an oil/nile blue sulphate agar medium[8], to be actively lipolytic, and were also found capable of utilizing a variety of lipids as carbon sources. When tested on a cellulose-containing medium[9], *C. thermophile* was found to be highly cellulolytic, while the other species were not.

These observations indicate that the three organisms are well adapted to growth in the highly specialized environment from which they have been isolated. In view of their lipolytic nature, these thermophilic fungi may play a significant part in the biodeterioration of oil palm produce during processing and storage[10], which is a problem of considerable importance in Nigeria and other producer countries.

Influence of Nitrogen Nutrition on Bud and Rhizome Development in *Agropyron repens* L. Beauv.

A PRELIMINARY investigation of the effect of the nitrogen supply on the growth of *Agropyron repens* L. Beauv. showed that reducing the nitrogen level caused an increase in the number of rhizomes produced. This increase in rhizome production was associated with a marked suppression of tillering and seemed to have resulted from a tendency for buds to develop as rhizomes rather than as tillers at the lower nitrogen-levels. A further experiment was therefore designed to investigate this effect more critically.

Seeds were germinated on moist filter paper at an alternating temperature of 15°–25° C and an 8-h photoperiod. The seedlings were selected for uniformity when the coleoptile was approximately 1 cm in length and were planted in 5-in. plastic pots containing 16-mesh quartz sand previously washed with distilled water. The sand was irrigated with Hoagland's solution[1] modified to provide a low nitrogen-level of 2·1 p.p.m. and a high level of 315 p.p.m., these concentrations being obtained by equimolar substitution of K_2SO_4 and $CaCl_2$ for KNO_3 and $Ca(NO_3)_2\ 4H_2O$ respectively.

Twenty plants were grown at each of these nitrogen-levels throughout the experiment. A third set of plants was changed from the low to the high nitrogen-level when the bud in the axil of leaf 1 had just emerged. Previous observations had established that this bud may develop either as a rhizome or as a tiller, being rather variable in this respect. In the present experiment the bud emerged from the base of the leaf sheath in 18 of the 20 plants and was clearly developing as a rhizome. These plants received the increased nitrogen supply when the young rhizomes were still only 1–3 mm in length. In the two remaining plants of this treatment the bud developed as a tiller and the high nitrogen solution was provided when the tiller emerged from the top of the leaf sheath.

The appropriate nutrient solutions were applied in excess at 2-day intervals, evaporation losses being replaced with demineralized water. The experiment was conducted in the greenhouse during the autumn of 1963. A bank of sixteen 8-ft. ('Gro-lux') fluorescent tubes extended the photoperiod to 18 h and provided an additional light intensity of 1,500 ft.-candles. The temperature ranged from 13° to 40° C during the day and from 10° to 21° C at night.

Final observations on bud development were recorded when the sixth leaf of the primary shoot had fully emerged. It is clear from the data in Table 1 that the mode of development of the bud in the axil of leaf 1 was largely determined by the nitrogen supply. At the low nitrogen-level, 90 per cent of these buds developed as rhizomes and 5 per cent as tillers; whereas at the high level of nutrition these proportions were approximately reversed, only 20 per cent developing as rhizomes and 70 per cent as tillers.

Table 1. EFFECT OF THE NITROGEN-LEVEL ON BUD AND RHIZOME DEVELOPMENT IN *Agropyron repens* L. BEAUV.

The data refer only to the bud in the axil of leaf 1

	% buds* developing as:		
Nitrogen-level	Rhizomes	Rhizomes with terminal shoot	Tillers
Low	90 (18)	5 (1)	5 (1)
High	20 (4)	10 (2)	70 (14)
Low to high†	42 (8)	47 (9)	11 (2)

* Number of buds shown in parenthesis.

† Percentages based on 19 plants, one plant having died.

Where a change from low to high nitrogen was made at the bud emergence stage 47 per cent of the young rhizomes, after reaching a length of 1–3 cm, were transformed into shoots. The upward curvature of the rhizome which preceded the transition from rhizome to shoot development was first apparent 5–8 days after the nitrogen supply had been increased.

Data on the behaviour of the bud in the axil of leaf 2 showed a similar effect of the nitrogen supply. At the high nitrogen-level all these buds developed as tillers, while 45 per cent developed as rhizomes at the lower level.

Subsequent experiments, in which similar nitrogen-levels were used, have given essentially the same results in spite of large differences in other environmental factors such as temperature and light intensity. It is therefore apparent that the nitrogen supply is a morphogenetic factor of considerable significance in bud development and seems likely to play an important part in controlling the balance between rhizome and shoot production.

Rhizome behaviour in this species has also been examined by Palmer[2], who showed that the formation of a terminal shoot can be experimentally induced by orientating the rhizome so that the apex points vertically upwards. He also showed that isolated rhizomes, which normally give rise to a terminal shoot, can be prevented from doing so and will continue to grow as rhizomes when rotated on a klinostat. This gravitational influence, when considered in relation to the well-defined nutritional effect revealed by the present experiment, raises the question as to whether these two effects are in some way related or whether the mechanisms involved are physiologically distinct.

It will also be of interest to determine the extent to which the results of the present investigation are applicable to other rhizomatous species.

This work (Scientific Paper No. 2762) was conducted under Washington Agricultural Experimental Station's Project No. 1479. I thank Dr. T. J. Muzik for kindly providing the necessary facilities in his department.

A Semi-quantitative Method of Counting Nematode-trapping Fungi in Soil

The usual method of observing nematode-trapping fungi in soil, as outlined by Duddington[1], consists of sprinkling soil in a Petri dish, dispersing in cool but still liquid agar medium, and then examining the whole dish for the trapping structures of these fungi after several days of incubation. Because of the uneven size and distribution of soil particles, and the large area to be examined, this method is difficult and unreliable as a means of estimating numbers of trapping fungi present. However, as outlined here, an adaptation of this method can be used to obtain semi-quantitative estimates.

As a first step in this method, each soil sample is reduced to a slurry or mud of even consistency by mixing in a Waring blender with an approximately equal volume of water. A 0·5-ml. aliquot of each slurry is then pipetted into an empty Petri dish and dispersed in 30 ml. cooled but still liquid 3 per cent water agar. Long narrow strips (3 mm × 60 mm are convenient) of the hardened soil—agar mixtures are cut from these dishes by means of two scalpels tied together with blades parallel. These strips are transferred by spatula to the centres of empty Petri dishes, and the plates are then flooded with 30 ml. of 'Difco' corn meal agar adjusted to 10 per cent of the specified concentration of nutrients. Finally, 1-ml. volumes of a water suspension of saprophytic nematodes are pipetted over the soil—agar strips. The dishes are then set aside to incubate.

Several species of saprophytic nematodes from soil can be grown in Petri dishes in an agar medium supporting good growth of common soil bacteria on which the nematodes feed[2]. The nematodes can later be extracted from this medium by a modified Baermann funnel[3] and standardized to approximately 1,000 nematodes per ml. of water.

After several days of incubation, the soil—agar dishes are examined for the presence of trapping structures in hyphæ which have grown out from the soil—agar strips. Provided these examinations are made in areas close by and parallel to the soil—agar strips, and before extensive branching of hyphæ has occurred, it is generally possible to distinguish between hyphæ originating from separate loci within the strips. Such hyphæ bearing one or more trapping structures are each given a count of one. The low nutrient content of the corn meal agar is a distinct aid in these examinations, both in reducing the extensiveness of branching in hyphæ of trapping fungi, and in reducing growth of contaminating fungi.

By standardizing the procedure described here, counts per dish can be converted to counts per gram of soil. They are then directly comparable to other microbial counts obtained by conventional soil-dilution plating techniques.

We have obtained estimates of nematode-trapping fungi in soil from a replicated field-plot experiment in which soil-treatment variables consisting of plant trash incorporation and nematocide fumigation both significantly affected populations of these fungi.

We thank the Director of this Institute for permission to publish these results.

Induction of Phototaxis in *Chlamydomonas snowiae* by Indolyl-3-acetic Acid and Ethylenediamine Tetraacetic Acid

In a previous report it was shown that acetic acid and certain other substances could prevent a phototactic response of cells of *Chlamydomonas* without impairing their motility[1]. It was of interest to see whether the reverse action could also be obtained, that is, to induce phototaxis in motile cells which do not respond to light. It will be shown that indolyl-3-acetic acid (IAA) and ethylenediamine tetraacetic acid (EDTA) induce such responses.

The cultures of *Chlamydomonas snowiae* were grown and handled, and phototaxis was measured as previously described[1–3]. The medium containing the algae was adjusted to the required *p*H with hydrochloric acid or potassium hydroxide. In the controls phototaxis was then assayed while to the experiments a suitable amount of the reagent was added and the *p*H checked again.

The effect of IAA on the phototactic response of a fully motile culture of *Chlamydomonas snowiae* is shown in Table 1. The response to IAA is seen to be dependent on concentration and *p*H. Clearly IAA is effective in the non-ionized form, presumably because it is this form which penetrates into the cell. IAA at concentrations between 10^{-3} and 10^{-4} M was able to induce phototaxis at *p*H 6·0 in about 45 out of 50 replicates of the experiments. In a few cases, about 5–10 per cent of the replicates, it failed to induce phototaxis in motile culture, apparently because lack of phototactic response was due to other causes. Analogues of IAA, indole butyric acid and indole propionic acid as well as naphthalene acetic acid and 2,4 dichlorophenoxyacetic acids were also effective, but higher concentrations were required and the induction of response was less consistent than with IAA.

Table 1. Induction of Phototactic Response by IAA at Various Concentrations and Various *p*H

*p*H IAA conc. M	5·4	5·6	5·8	6·1	6·3
0 (control)	−	−	−	−	−
10^{-4}	+ + +	+ + +	+ + +	+ + +	+ + +
$2 \cdot 10^{-5}$	+ +	+ + +	+ + +	+	−
10^{-5}	+ + +	+ +	+ +	−	−
10^{-6}	±	±	−	−	−

−, no response. +, positive response. + + +, very strong response.

Not only did IAA induce phototaxis, but it was also able to reverse to a considerable extent the inhibitory action of acetic acid on the phototactic response. The phototactic response of a culture responding well to light was inhibited by the addition of acetic acid at *p*H values between 6·0 and 5·2. Addition of 10^{-4} M IAA did not reverse the inhibitory action. However, when the IAA concentration was raised to 10^{-3} M, then phototaxis was fully restored between *p*H 5·8 and 5·4 and almost fully at *p*H 6·0 and *p*H 5·2. IAA did not reverse the action of detergents such as 'Tween 80' on phototaxis. Reversal of inhibitory effects could also not be obtained consistently by the IAA analogues.

Other compounds were tested for their ability to induce phototactic response in motile, non-responding cultures of

Chlamydomonas; EDTA at a concentration of 5×10^{-5} M and 10^{-5} M had the same effect as IAA. At higher concentrations, 10^{-4} M and above, EDTA inhibits motility of the organism. The action of EDTA was not so sharply *p*H dependent as that of IAA, being equally effective at *p*H 6·0 and 5·6 at a concentration of 5×10^{-5} M.

It is at present difficult to conjecture about the possible mode of action of IAA and EDTA in inducing phototactic responses and in reversing the inhibitory action of acetic acid. Probably IAA does not act here as a conventional hormone. Although both IAA and EDTA can act as chelates, for example, of calcium it seems unlikely that they do so here, in view of the *p*H range in which they are active and the very weak chelating capacity of IAA. However, it must be noted that IAA and EDTA may be regarded as derivatives of acetic acid. This, together with the interaction of IAA with the latter, makes it possible that they compete for some specific site within the flagella or cell. This site would determine the correct translation of the impulses sent from the light receptor into the flagella. Correct translation results in flagellar beat such as to orient the organism toward the light; prevention of translation also prevents oriented movement.

Actions and Dosage of Chloralose

Many books recommend chloralose as an anæsthetic for laboratory animals and give a dosage rate of 40–80 mg/kg body-wt.; the drug is considered particularly useful for animals in which autonomic reflexes are to be preserved. I have recently carried out a series of experiments in the dog and rabbit, and in no case did surgical anæsthesia result from intravenous injections of 70 mg/kg or less. If chloralose was used after induction with ether slight improvement was seen, but surgery was still not possible. The heart rate was slowed by 30 per cent in these experiments and excessive secretions caused respiratory embarrassment.

The action of chloralose has not been well understood in the past: "The action is a remarkable one, for the animal does not appear to pass beyond a stage of narcosis, and paddling movements of the legs or nodding of the head may appear throughout. . . . It is suggested that the condition is possibly one of hypnosis superimposed on narcosis, rather than anæsthesia"[1]. Electrocorticographic recordings now show that it makes the Betz cells susceptible to sensory stimuli[2], and that the convulsive response to slight stimulus which readily occurs under chloralose is a cortical reaction, for "chloralose, like the convulsants, facilitates transmission in a reflex arc including the cortex"[3]. Grieg[4] described these convulsions as "strychnine-like". Shukla *et al.*[5], studying its effect on autonomic reflexes, found that it slowed the heart rate by 50 per cent, while Kochmann[6] found that "it reinforces some actions of epinephrine and acts like atropine in reducing vagal activity".

In view of the fact that chloralose does not affect the electrical activity of the brain in the same way as other drugs known to be general anæsthetics, and bearing in mind that it does not leave autonomic reflexes unaltered, it would seem that some substitute should be sought for this drug; a great variety of new substances acting on the central nervous system have been developed since the Second World War, and traditional procedures may not be justified in the light of present knowledge. The fact that chloralose is not used in human medicine casts further doubt on the validity of its use as an anæsthetic for laboratory animals.

Some Negative Results in the Search for a Lethal Effect of Magnetic Fields on Biological Materials

During recent years there has been an increasing number of reports in the literature of the ability of magnetic fields to affect biological systems. Gerencser and Barnothy[1] noted differences from control of cultures exposed to 15,000 gauss, while Butler and Dean[2] found growth inhibition in tissue culture of *KB* cells exposed to 4,000-gauss magnetic fields. Maclean[3], using intense and 'mild' magnetic fields of unspecified strengths, reported various effects on tumour-bearing mice, but since only 12 animals were used for the entire investigation and these were divided into 3 groups, the results can have no statistical significance. Negative reports have appeared too, and in the most recent of these Halpern and Greene[4] reported that the growth rate of HeLa cells cultured in a 1,200-gauss magnetic field was not significantly different from controls. This communication extends this negative finding to much higher magnetic field strengths. Three separate experiments were performed, using HeLa cells cultured *in vitro*.

The cells were cultured by the methods described elsewhere[5]. In each experiment 200 cells were inoculated into either 50 mm 'Falcon' plastic Petri dishes or into 'Falcon' plastic culture flasks. Two containers were reserved for controls and two were subjected to a magnetic field for various lengths of time as detailed here. The cells were afterwards incubated for 10 days at 37° C in an incubator continuously flushed with a mixture of 5 per cent carbon dioxide and 95 per cent air. At the end of this period the cells were fixed with 10 per cent formalin in normal saline, stained with crystal violet, and the number of macroscopic colonies on each dish or flask counted. The following treatment conditions were used.

(*a*) A steady field of 5,000-gauss was obtained with a permanent magnet having 2-in. diameter pole pieces which were just large enough to cover the 50 mm plastic Petri dishes. The magnet was mounted inside the incubator and the treated plates were subjected to the magnetic field throughout the 10-day period of incubation. The control plates were kept in the same incubator at approximately 12 in. from the pole pieces. Approximately 150 colonies were counted in each dish, but there was no significant difference between the number of colonies counted on the treated against the control dishes (Table 1). There was no obvious difference in the size of the colonies, or their morphology.

(*b*, *c*) To obtain stronger magnetic fields, it was necessary to use electromagnets. Consequently it was not possible to mount the magnets inside the incubator and, for this and other reasons, treatment times were much shorter.

In one experiment an electromagnet was used which had tapered pole pieces, 4-in.–2-in. diameter, with a gap between the poles of 15 mm. Two culture flasks were exposed to a magnetic field of 27 kilogauss for a period of

Table 1

Exp.	Field strength (gauss)	Time of exposure	No. of colonies on control dish or flask	No. of colonies on treated dish or flask
(*a*)	5,000	10 days	150	149
			145	158
(*b*)	27,000	1 h	168	175
			180	165
(*c*)	77,000	15 min	143	161
			151	148

1 h. In another experiment, two culture flasks were placed inside a solenoid, 2-in. diameter, and exposed to a magnetic field of 77 kilogauss for a period of 15 min. In both cases control cultures were handled in a similar manner except that the magnets were not energized. In both experiments, approximately 150 colonies were counted on both treated and control flasks, there being no significant difference between them, either in cell number or morphology (Table 1).

It would seem, therefore, that gross lethal effects on mammalian cells are not produced either by powerful magnetic fields applied for short periods, or by lower field strengths extending over many cell generation times, The work recorded here is subject to the same fundamental limitation as previous reports in the literature—namely, the necessity of using permanent magnets for long-term experiments, with a consequent limit to the field strength of 5–15 kilogauss. For fields higher than this, it is necessary to use electromagnets which consume such vast quantities of electrical power that long-term experiments are out of the question. An obvious alternative would be to use super-conducting magnets, which can provide fields of the order of 50 kilogauss for extended periods at a nominal cost.

We thank Dr. F. Ellis for his advice; Prof. B. Bleaney for the use of the facilities in the Clarendon Laboratory; Dr. N. Kurti and Mr. M. F. Wood for the use of the high-power solenoid; and Mr. J. Good for assistance in the high-field experiment.

A Persistent Diurnal Rhythm in Photosynthetic Capacity

IN 1939, Meyer[1] discovered a daily rhythm in the rate of photosynthesis in *Ceratophyllum*, a fresh-water angiosperm. In 1957, similar rhythms were found in natural populations of marine phytoplankton[2,3]. Four years later, Hastings *et al.*[4], working on the photosynthetic-capacity rhythm in the marine dinoflagellate *Gonyaulax*, demonstrated that these rhythms would persist for a few days in the laboratory in the absence of day–night environmental cycles, that is, in continuous dim illumination and constant temperature. Negative evidence was presented by Blinks and Givan[5], who performed experiments which suggested the absence of photosynthetic rhythms in 13 species of marine littoral algae. In view of the different results, we have undertaken comparative investigations in an attempt to establish the distribution of persistent rhythms in marine flora.

Pure cultures of the marine diatom, *Phaeodactylum tricornutum*, were used in the work reported here. Cultures of this algae were grown in Guillard's medium *f* (ref. 6) and maintained in a light régime of 12 h of illumination (600 ft.-candles from 'cool white' fluorescent tubes) alternating with 12 h of darkness. When the cultures approached the stationary phase of growth, periodic measurements of photosynthesis were commenced. At the midpoints of each light and dark period, 3 or 4 10-ml. samples were withdrawn from a parent culture and incubated with 1 μc. $Na_2C^{14}O_3$ for 15 min at 600 ft.-candles. Usually, one of these samples served as a 'dark bottle' control, that is, it was incubated in the dark and used to correct for any adsorption of carbon-14 on the cells, etc. At the end of the incubation period the reaction was stopped by adding 2-ml. 1 N hydrochloric acid to the sample; the cells were then collected on a 'Millipore' filter, washed with 5-ml. 0·1 N hydrochloric acid, dried in a desiccator, and the uptake of carbon-14 measured. Concurrently, aliquots of the culture were extracted with methanol and the chlorophyll *a* content determined spectrophotometrically. Cell counts were also made at each sampling time.

This method measured the capacity, or the rate, at which the algae could maintain photosynthesis under a given set of conditions; and, in the experimental design described here, compared the rate at which photosynthesis could proceed at night (when, of course, the photosynthetic machinery is normally inactive) with the midday rate. Fig. 1 shows the results of these measurements; photosynthesis was maximal during the light period and minimal during the dark period, the difference being more than three-fold. (Using identical methods, we found a similar rhythm in the dinoflagellate, *Gymnodinium nelsoni*.) It is clear that some physiological change must have taken place in the cells, which resulted in an altered capacity of the cells to maintain photosynthesis. This change could have been induced in the cells by the different light conditions to which they were subjected (either 6 h of light or darkness) immediately prior to the time at which the rate-measurements were made; or the fluctuations could be controlled by a biological clock, the oscillations being relatively independent of light–dark cycles. By following photosynthesis in cells maintained in continuous illumination—as was done in the next experiment—this problem was resolved.

Cultures were now first grown in alternating cycles of light and darkness for 10 days and then placed in either continuous darkness or in various intensities of continuous light. On the 2 days prior to placing the cultures in static conditions, periodic photosynthetic-rate measurements were made to make sure a rhythm was present; this done, the cultures were then placed in continuous light or darkness at a constant temperature (15° C). As before, and

Constant darkness	1·16	0·05	1·12	0·10
20 ft.-candles	1·37	0·18	1·54	0·23
40 ft.-candles	1·52	0·26	1·53	0·29
80 ft.-candles	1·44	0·21	1·60	0·21

$\bar{x}$, mean of 4–5 chlorophyll determinations. *S.D.*, standard deviation.

in exactly the same manner, photosynthetic rates were determined at 12-h intervals. The results are seen in Fig. 2. In constant darkness the rhythm is not expressed. At 20 ft.-candles, one oscillation—about halved in amplitude—occurs and then all indication of the rhythm disappears. At 40 and 80 ft.-candles, the rhythm will persist for at least three cycles and is characterized by a gradual damping out. As is universally the case of biological rhythm, continuous bright light (600 ft.-candles in this case) inhibits the expression of the rhythm.

The photosynthetic rhythm could well be an indirect result of an underlying rhythm in photosynthetic-pigment content. Mitrakos *et al.*[7] have demonstrated the presence of just this sort of rhythm in the angiosperm *Perilla ocymoides*. They found that the carotenoid and the chlorophyll *a* and *b* content of this plant fluctuated in a diurnal pattern; and that these rhythmic fluctuations would persist in constant light and temperature. Yentsch and Ryther[3] also found diurnal variations in chlorophyll content and in the rate of chlorophyll synthesis, the maxima of which corresponded to the maxima in the photosynthetic rhythm they were investigating. On the other hand, Hastings *et al.*[4], working on the photosynthetic rhythm in *Gonyaulax*, found no change in either the peridinin (the main carotenoid of this dinoflagellate) or the chlorophyll content, which corresponded to the rhythm in photosynthesis. Doty and Oguri[2] report similar findings. Table 1 depicts the differences that we found in chlorophyll *a* content in the various points of the cycles reported here. It is obvious that these differences are not responsible for the photosynthetic rhythm in *Phaeodactylum*; in fact, the day-time chlorophyll values were slightly lower than the night-time ones; but, as can be seen from the size of the standard deviations, the values are not significantly different from one another.

The data also suggest a rhythm in cell division, for virtually all increases in cell number took place during the last half of the dark period and the first half of the light period. Population increases also continued to take place in the same manner in constant conditions. Sweeney and Hastings[8] have reported a similar rhythm in *Gonyaulax*.

VETERINARY SCIENCE

Enzootic Abortion of Ewes

Enzootic abortion of ewes (EAE) was originally described in Scotland by Stamp *et al.* in 1950[1], and since then the disease has been recognized in several other countries including the United States. The disease has recently been observed in California[2]. A somewhat analogous disease of cattle—epizootic bovine abortion (EBA)—has been recognized in this State for many years. Both diseases are caused by members of the psittacosis lymphogranuloma-venereum (PLGV) group of agents. The placenta is the primary site of predilection for the multiplication of the EAE agent, and the resulting placentitis is presumed to lead to abortion. In EBA, placentitis, although occasionally present, is not so obvious as the changes in the fœtus itself which include a generalized vasculitis with widely distributed petechiæ and focal, generalized hyperplasia of the reticuloendothelial system[3]. The birth of premature, weak young, many of which fail to survive, is a feature of both diseases.

During investigations primarily concerned with the cattle disease, pregnant ewes were inoculated with the agent of EBA. The resulting syndrome in these ewes differed in no substantial way from that of EAE. We did, however, recognize histological changes in the aborted ovine fœtuses. Afterwards, EAE was recognized as a naturally occurring disease in local sheep and the EAE agent was recovered. A group of pregnant ewes was inoculated with this agent, and when these ewes later aborted tissues from their fœtuses were also examined. It is our purpose here to describe briefly the histological changes which have been observed in ovine fœtuses aborted as a result of infection with either EBA or EAE agents.

No gross lesions were observed in the aborted fœtuses although some, which had

British Special Quality Valves and Electron Tube Devices Data Annual 1964–65

Edited by **G.W.A.Dummer** and **J.Mackenzie Robertson**, Royal Radar Establishment, Malvern, Worcestershire

The increasing emphasis on reliability of electronic equipment has led to the development of many types of special quality valves. Their use is widespread – despite the increasing use of transistors – so that a comprehensive source of data on their characteristics is essential. This volume provides designers and users with complete data on a wide range of special quality valves. It also makes available information on many types of special electron tubes and devices – cathode ray tubes, photocells, counters, electroluminescent panels, klystrons, magnetrons and stabilisers. The work constitutes an invaluable source of reference for designers and users of all types of electronic equipment.

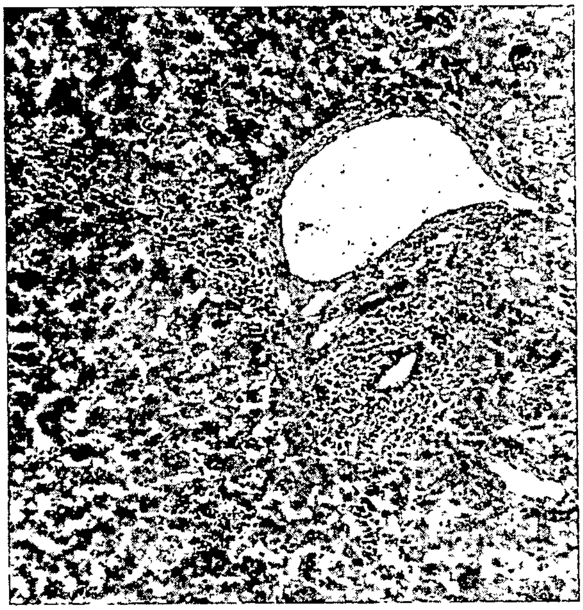

Fig. 1. Perivascular accumulation of reticuloendothelial cells in the liver of a lamb fœtus infected with epizootic bovine abortion agent. The discrete, darkly staining cells are hæmopoietic elements

died and autolysed *in utero*, had blood-stained fluid in the serous cavities. Microscopically, focal accumulations of reticuloendothelial cells were present in the organs and tissues of most aborted fœtuses. In some foci, particularly where necrosis was present, moderate numbers of neutrophils were also present. The foci were always oriented around blood vessels, and in the liver these reactive cells formed thick cuffs around the vessels of the portal triad. Any tissue of the body could be involved in any one fœtus, but the distribution, size, and incidence of the changes were not consistent. The liver was the organ most regularly involved. The proliferated reticuloendothelial elements were often present with the more darkly staining hæmopoietic cells (Fig. 1). Differentiation was usually possible on the basis of distribution and tinctorial quality. Among the other organs in which these reactive foci were observed were : lung, kidney, spleen, lymph node, heart muscle, and skeletal muscle. Occasionally, aborted fœtuses did not have demonstrable changes in their internal organs even though typical elementary bodies were observed in placental smears.

In parallel with the histological examinations, isolation of the agent from various fœtal tissues in the yolk sacs of embryonating hen eggs confirmed the presence of the agent in those tissues in which the pathological changes were occurring. Complement fixation tests on the sera of the dams, bacteriological examination of fœtal tissues and inoculation of pregnant ewes with normal yolk sac material further confirmed that the changes present in the aborted fœtuses were in fact the result of invasion by either the EBA or the EAE agent.

It should be emphasized that placentitis is the major pathological change seen when pregnant ewes are infected with either EAE or EBA agents, but the presence of lesions in the internal organs of lambs born to infected ewes may be important in the neonatal mortality seen in EAE. It is unlikely, however, that these changes are a specific response. Indeed, similar changes have been described in lamb fœtuses aborted as the result of toxoplasmosis[4]. In general a period of at least 60 days intervened between experimental inoculation of EAE or EBA agents and expulsion of the fœtus. It is felt that there is an immunological basis for the lesions related to the engulfment of antigen by reticuloendothelial cells. Because the antigen persists and increases within the cell it is not in fact effectively removed by the macrophages. The generalized distribution of the changes in the fœtus indicates that invasion of the fœtal blood stream occurs. These observations again direct attention to the very close relationships that exist among various members of the PLGV group of agents—particularly those that have been implicated in various diseases in ruminant animals.

We thank Dr. D. G. McKercher for his co-operation. This work was supported by grants from the U.S. National Institutes of Health and the U.S. Department of Agriculture.

Inhibitory Effect of Lactation on the Breeding Activity of the Ewe

In the course of investigations on the natural breeding activity of a flock of 'Clun' sheep on the College Farm, 37 cases have been recorded, over several seasons in which entire rams have run continuously with the flock, of ewes lambing in one season and conceiving again in the same season. Some of these ewes have lambed in the autumn and conceived again in the winter, and others have lambed in the late winter and conceived again in the spring.

From results available it is possible to compare the inhibitory effects of lactation on renewed breeding activity according to time of lambing. This is shown in Fig. 1.

Of 21 ewes considered to be autumn lambers, all were successfully mated again during the winter with a mean number of days from lambing to next conception of 41·86 ± 2·29 days. Moreover, with the exception of one ewe which lost its single lamb at birth, all these ewes were in full lactation at the time of next conception. The mean autumn lambing date was November 2 ± 6·72 days.

Of 16 ewes considered to be late winter lambers, which were successfully mated again in the spring, the mean number of days from lambing to next conception was 137·6 ± 4·78 days. All the ewes lambed by January 30, the mean lambing date being January 13 ± 2·25 days, and the majority, 13 out of 16, were weaned completely by April 16. In the case of one ewe, partial weaning occurred on April 16 by the removal of a larger lamb

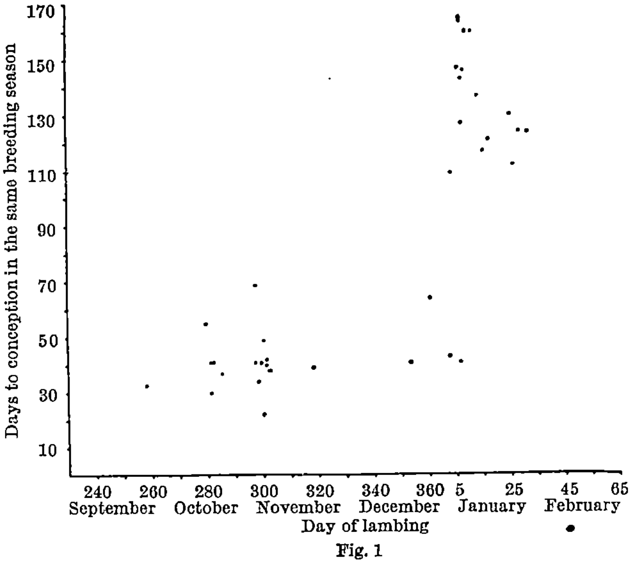

Fig. 1

from a set of twins, allowing a considerably smaller lamb to remain for a much longer period extending beyond the next conception. In the case of the remaining two ewes, which were not weaned until mid-summer, conception took place while they were still suckling. The mean number of days to weaning of 13 completely weaned ewes was 76 ± 3·56 days and from weaning to next conception 61·8 ± 3·96 days.

Twenty-eight flock contemporaries also lambed in January and were weaned by April 16; but they failed to breed again in the same season. 75 others either lambed later than January 30 or were weaned later than April 16, or both. None of these bred again in the same season.

The difference between the mean 'conception periods' (the number of days from lambing to fertile mating) for the autumn and late-winter lambing groups is very highly significant ($P < 0{\cdot}001$) and the change appears to be a very abrupt one occurring at about the turn of the year.

It has not been possible to discriminate between accidental failure and physiological inability to breed. The measurement of renewed breeding activity in terms of actual conception, that is, of effective mating, may thus include a component of error in respect of returns to service due to any accidental failure to conceive (or to early embryonic loss). On the other hand, simply to accept mounting by the ram as an indication of renewed ability to breed could be wholly misleading. Some of these ewes have been pursued or mounted by the ram within 24 h of parturition—others within a few days. In fact, one new-born lamb was lost due to the persistent interference of a ram. But it is very unlikely that mating at such an early stage would be successful and it could not be concluded from mating behaviour by itself that the inhibitory effect of lactation on further breeding ability had ceased. Nevertheless, it is interesting to speculate that, in certain cases among the 21 autumn lambers, for example, the longer 'conception periods' might be attributable to accidental failure to conceive at an earlier œstrus, since, in the four cases where the time to successful mating was 49 days or more, subtraction of average cycle lengths would reduce their recorded 'conception periods' to approximately 38, 36, 33 and 31 days, bringing them very close to a revised mean of approximately 37 days.

The effect of 'lactation anœstrum' thus appears to be markedly different between the two halves of the breeding season. During the period of shortening day-length the increasing intensity of breeding activity may be sufficient partially to offset the effects of 'lactation anœstrum', which then reasserts its influence as the days begin to lengthen, and breeding intensity declines.

It is concluded that the pattern of the breeding behaviour of 'Clun' ewes is not wholly inflexible but can to some extent be manipulated by management practices, particularly early lambing coupled with early weaning, which in this case has resulted in a high proportion (16/44 or 36·4 per cent) of the ewes so treated conceiving again in the same breeding season.

The genetic aspects of this matter and the possibility of selecting for individuals more likely to conceive again after lambing have yet to be examined further.

ENTOMOLOGY

Secretory Activity in the Corpora Allata of Worker Honey-bees (*Apis mellifera* L.)

The corpora allata are among the endocrine organs in insects controlling larval development[1]. These organs are also active in the adult stage, exerting effects on metabolism and in some insects on the reproductive organs[2].

Volumetric measurements of the corpora allata in adult bees have shown them to be almost twice as large in worker as in queen bees, but no conclusive evidence of secretory activity has been noted[3-6]. In recent work on the salivary glands in worker bees such secretory activity of the corpora allata was observed, and is reported here.

Table 1. RESULTS OF THE EXAMINATION OF THE CORPORA ALLATA OF WORKER BEES AFTER VARIOUS FIXATIVES

Fixatives	No. of bees examined	No. of bees with secretion granules in the cells of the corpora allata
Bouin's (alcoholic)	84	3
Formalin (neutral)	30	2
Zenker's (acetic acid)	52	4
Total	166	9

Adult worker bees from a normal honey-bee colony were fixed at daily intervals in alcoholic Bouin's, neutral formalin and Zenker's fixatives. The age of these insects ranged from 1 to 25 days after emergence. After embedding in methacrylate the specimens were sectioned at 8 microns by the use of the tape method[7]. The histological material was stained by the standard hæmatoxylin and eosin method or Gomori's chromium hæmatoxylin–phloxin stain[8]. From a total of 166 bees examined, 9 animals (5·4 per cent) showed phloxinophilic granules within the cytoplasm of the cells of the corpora allata. Such granules were seen with all fixatives and stains, as reported in Table 1, and illustrated in Fig. 1. The granules within the cells of the corpora allata were noted principally in bees between the ages of 18 and 25 days; in two instances, however, the granules appeared in worker bees at 2 and 5 days following emergence. The phloxinophilic granules were observed near the nuclei of the cells. The structure of such nuclei was quite different from that of nuclei in cells lacking secretory granules. The chromatin was concentrated at the marginal portion, leaving the central area either 'empty' or occupied by one large or several small phloxinophilic inclusions (Fig. 1). These inclusions may be nucleoli.

The secretion granules appeared to be a product of the corpora allata; in no instance was it observed that the granules originated from some other source (that is, the brain or the corpora cardiaca).

It is possible that the granules are released from the corpora allata into the blood. The physiological impor-

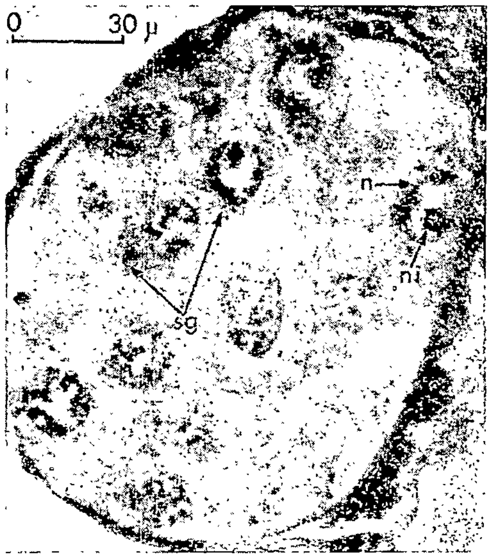

Fig. 1. Photomicrograph of a corpus allatum of an adult worker bee showing secretion granules (*sg*), nucleus (*n*) and nuclear inclusion (*ni*). Thickness of section, 8μ; fixative, alcoholic Bouin's; stain, Gomori's chromium hæmatoxylin

tance of this secretion is unknown, and since the secretion granules were seen in only a few worker bees, it is difficult to interpret their significance. However, this communication supports the claims of other investigators that the corpora allata are secretory organs in adult worker bees.

MICROBIOLOGY

Antibiotic Sensitivity and Bacterial Numbers

IT is known that the size of inoculum affects results in tests of bacterial sensitivity to antibiotics[1,2]. This is due to individual differences in the bacterial population; the greater the number exposed to a certain concentration of antibiotic, the greater the likelihood that one organism may grow out.

Experiments were carried out in order to establish a quantitative relationship between size of inoculum and inhibiting concentration of antibiotic. Two antibiotics, penicillin and streptomycin, and seven strains of *Staphylococci* (*epidermidis*, *aureus*, 52*A*, 79, 80, 81 and *MG*, a clinical isolate), were investigated. The dilution method was used. Each test-tube contained 10 ml. 'Trypticase Soy Broth' (Baltimore Biological Laboratory). So as to compensate for the dilution caused by the addition of antibiotic, contained in 1 ml. water, and by the addition of the inoculum, also contained in 1 ml. fluid, the powder was dissolved in 80 per cent of the prescribed amount of water. Sixteen to eighteen-hour-old cultures served as inoculum. Bacterial numbers were estimated from optical densities, obtained at 640 mμ[3,4], and appropriate dilutions were prepared. The inocula, per 10 ml., were of the order of: 10^1. 10^2, 10^3, 10^4, 10^5, 10^6 and 10^7. Absence of growth was recorded after incubation for 18 h at 37° C. Preliminary experiments with varying concentrations of antibiotic and varying numbers of bacteria were carried out in order to find the range in which inhibition occurs. Then 20–22 different concentrations of antibiotic, closely spaced, were inoculated with each of the seven inoculum sizes. Each experiment was carried out at least three times.

The mean inhibitive dose, per ml., of penicillin and streptomycin, for two inoculum sizes, namely 10^1 and 10^7, of strains 79, 80, 81 and *MG*, are shown in Table 1. As *Staphylococcus epidermidis*, *aureus*, 52*A* and 79 gave similar results, 79 was chosen to represent the group.

From Table 1 it can be seen that the range of inhibitive doses for penicillin-resistant strains is extremely wide. The penicillin dose needed to suppress growth with an inoculum of 10^7 is 1,000–4,000 times greater than that needed for suppressing growth with an inoculum of 10^1. On the other hand, the range for penicillin-sensitive strains (79) is rather small; the dose is only doubled for inocula ranging from 10^1 to 10^7.

As to streptomycin, inoculum size does not play such a decisive part, even in resistant strains.

Table 1. MEAN INHIBITING DOSES OF PENICILLIN AND STREPTOMYCIN PER ML. FOR INOCULA SIZES OF ORDER OF 10^1 AND 10^7

Penicillin in units, streptomycin in μg

Strain	Inhibiting dose per ml. of:	Inoculum per 10 ml. 10^1	10^7
79	Penicillin	0·033	0·07
	Streptomycin	1·00	6·00
80	Penicillin	0·60	800
	Streptomycin	40	2,000
81	Penicillin	0·60	650
	Streptomycin	1·75	17
MG	Penicillin	0·1	400
	Streptomycin	100	1,000

Table 2. COEFFICIENTS OF CORRELATION BETWEEN LOGARITHMS OF BACTERIAL NUMBERS AND LOGARITHMS OF INHIBITING DOSES OF PENICILLIN AND STREPTOMYCIN

Strain	Coefficient of correlation Penicillin	Streptomycin
79	0·792	0·938
80	0·928	0·894
81	0·877	0·929
MG	0·868	0·957

Table 3. REGRESSION LINES FOR LOGARITHMS OF BACTERIAL NUMBERS (x) AND LOGARITHMS OF INHIBITING DOSES (y)

Strain	Penicillin	Streptomycin
79	$y = 0{\cdot}07745\ x - 1{\cdot}67159$	$y = 0{\cdot}15663\ x - 0{\cdot}20302$
80	$y = 0{\cdot}50300\ x - 1{\cdot}18508$	$y = 0{\cdot}22467\ x + 1{\cdot}33165$
81	$y = 0{\cdot}46924\ x - 1{\cdot}34580$	$y = 0{\cdot}19199\ x - 0{\cdot}17431$
MG	$y = 0{\cdot}47270\ x - 1{\cdot}45345$	$y = 0{\cdot}17550\ x + 1{\cdot}67669$

When plotting the logarithms of bacterial numbers contained in the inocula versus the logarithms of the inhibiting doses of antibiotic, it became apparent that a correlation exists. The coefficients of correlation are shown in Table 2.

There exists a significant correlation between the logarithms of bacterial numbers and the logarithms of inhibiting doses.

When connecting two neighbouring points by a straight line, it was noticed that the resulting curves differed in slope. Regression lines, therefore, were calculated for all strains. Table 3 shows the regression lines.

The regression lines were tested for linearity. The variance ratios indicated that the curves did not differ significantly from straight lines; P values ranged from 0·003 to $< 0{\cdot}001$.

From the coefficients of regression it can be seen that in strains resistant to penicillin the slopes are similar, corresponding to angles of 25°–27°. The slopes for penicillin-sensitive strains correspond to angles of 4°–5°. For streptomycin-resistant strains the slopes correspond to angles of 10°–13°, and for streptomycin-sensitive strains, the angles vary from 8° to 9°.

Differences in slopes were tested for significance. It was found that slopes of penicillin-resistant and penicillin-sensitive strains differ significantly ($P < 0{\cdot}001$). As to streptomycin, there were no significant differences among slopes, irrespective of sensitivity.

In conclusion it may be said that the size of inoculum is of particular importance when testing strains resistant to penicillin. Depending on inoculum size (10^1–10^7), the penicillin dose needed to suppress growth may vary from 0·1 to 400 units per ml. This phenomenon may not be restricted to penicillin. It has been stated: "If 10^{-3} dilution is used for sulphonamide, no activity can be demonstrated", and 10^{-11} dilution is recommended[5].

Protective Effect of β-Carotene against Lethal Photosensitization by Hæmatoporphyrin

THE carotenoid pigments of certain bacteria can protect the micro-organisms against lethal photosensitization by visible light in the presence of the dye, toluidine blue[1,2]. Since mice can also be lethally sensitized to visible light by the administration of hæmatoporphyrin intraperitoneally, it seemed likely that injection of the carotenoid pigment, β-carotene, would protect against the lethal photosensitization.

An acetic acid–sulphuric acid derivative of hæmatoporphyrin–HCl was prepared by the method of Lipson and Baldes[3]. Suspensions of β-carotene in 'Tween 80' and saline were prepared according to the method of Forssberg *et al.*[4]. Male albino mice of the Charles River Laboratories strain, weighing 18–24 g, were anæsthetized with ether and given 0·2 ml. of suspensions containing 3 mg of β-carotene intraperitoneally. The β-carotene was given 18–24 h prior to exposure to light, in a volume of 0·2 ml. Hæmatoporphyrin (1 mg in 0·2 ml.) was injected in a similar manner just prior to exposure to light. The mice were exposed unshaven to the light from two General Electric blacklight bulbs (maximal emission between 3,400 and 4,400 Å), at a distance of 3·5 in. for 4 h. The mice were held in 0·5-in. wire mesh holders placed in parallel on a board.

Table 1. PROTECTIVE EFFECT OF β-CAROTENE ON PHOTOSENSITIZATION OF MICE BY HÆMATOPORPHYRIN AND VISIBLE LIGHT

Group	Light exposure	No. animals	No. dead	No. alive
Hæmatoporphyrin	Yes	27	21	6
Hæmatoporphyrin and carotene	Yes	27	9	18
Hæmatoporphyrin and 'Tween 80' saline	Yes	8	7	1
Hæmatoporphyrin	No	8	0	8
Carotene	No	8	0	8

Table 1 shows that β-carotene, injected intraperitoneally, protects against lethal photosensitization by the hæmatoporphyrin. The appropriate controls indicate that 'Tween'–saline suspensions are non-toxic, and afford no protection against photosensitization, and that hæmatoporphyrin is non-toxic to animals kept in the dark.

Forssberg *et al.*[4] showed that lycopene, another carotenoid pigment, protected mice against X-irradiation and suggested that the protective action of lycopene might be due to its particulate nature, as well as to some inherent chemical characteristic of the molecule. They were also able to obtain protection against the X-irradiation syndrome by the injection of zymosan, a polysaccharide prepared from yeast cell walls. Experiments were, therefore, performed to see if zymosan could afford any protection against lethal photosensitization of the mice by hæmatoporphyrin and light. Zymosan was injected in saline to give 3 mg/mouse in a volume of 0·2 ml. This amount was found by Forssberg *et al.*[4] to protect against X-irradiation. However, when the zymosan was injected intraperitoneally into mice 18–24 h before injection with hæmatoporphyrin followed by exposure to light, zymosan offered little or no protection against lethal photosensitization (Table 2).

Table 2. RELATIVE LACK OF PROTECTIVE EFFECT OF ZYMOSAN ON PHOTOSENSITIZATION OF MICE BY HÆMATOPORPHYRIN AND VISIBLE LIGHT

Group	Light exposure	No. animals	No. dead	No. alive
Hæmatoporphyrin	Yes	28	20	8
Hæmatoporphyrin and zymosan	Yes	28	17	11
Zymosan	No	8	0	8
Hæmatoporphyrin	No	8	0	8

Recent work has shown that the carotenoid pigments of bacteria are capable of protecting the cells against lethal photosensitization both by endogenous photosensitizers (hæms, chlorophyll) and exogenous photosensitizers (dyes)[1,2,5,6]. Carotenoid pigments are invariably found in bacteria that are exposed to light and air[6]. In green plants, carotenoids are closely associated with chlorophyll, which is a powerful photosensitizer; it is thought that these pigments protect the chlorophyll and other plant porphyrins from photodestruction, and prevent the chlorophyll and other porphyrins from causing cell damage[7]. Carotenoid pigments are also found in skin[8], the cells of which contain potential photosensitizers such as porphyrins and cytochromes. In view of these facts, and of the experimental findings presented here, it is suggested that carotenoid pigments play a part in protecting plant and animal cells against injury from exposure to visible light. This exposure to visible light is presumably injurious because of the presence of potential photosensitizers (such as hæms, porphyrins, cytochromes) within the cell.

The present experiments also suggest that carotenoid pigments might also be administered to patients suffering from skin diseases attributable to visible light. Carotenoids even in large doses seem to be harmless[9]; one successful attempt at carotenoid therapy for light-sensitivity has been reported[10].

This work was carried out during the tenure of a National Science Foundation post-doctoral fellowship, 1963–64, and supported in part by a grant from the Milton Fund of Harvard University. I thank Dr. E. H. Kass for the hospitality of his laboratory, and for his advice.

Relation of Ribonucleic Acid Composition to Growth Rate and Dormancy in *Bacillus subtilis*

RECENTLY, Kjeldgaard and Kurland[1] have shown with *Salmonella typhimurium* that the ratio of soluble RNA to DNA is constant at all growth rates, and that the increase in cell RNA content with increasing growth rates results from an increase in the ratio of ribosomal RNA to DNA. Protein synthesis was also directly related to the amount of ribosomal RNA present. The results of these investigations indicate that the ratio of soluble RNA to ribosomal RNA increased at lower growth rates. If this relationship between the two major RNA fractions of bacterial cells is consistent, one might expect a relatively high soluble RNA to ribosomal RNA ratio in spores which are a non-growing stage in certain bacterial species. An analysis of vegetative cells and spores of *Bacillus subtilis* was undertaken therefore to determine if this relationship between RNA composition and growth rate was maintained.

*Bacillus subtilis W*23 cells were grown at different rates in Difco 'Penassay' broth and in synthetic media (0·055 M NH_4Cl; 0·170 M NaCl; 0·054 M KCl; 0·006 M $MgSO_4$; 0·0025 M $PO_4^{\equiv}$; 0·0006 M $FeCl_3$; 0·050 M *tris* buffer, *p*H 7·2; 0·0001 M $MnCl_2$; and 0·0002 M $CaCl_2$), which contained 0·011 M glucose and 0·2 per cent casein hydrolysate (*SCM*-1), 0·011 M glucose (*SCM*-2) or 0·8 per cent sodium glutamate (*SCM*-3) as the energy source. Good sporulation was obtained only in the Difco 'Penassay' broth and the *SCM*-1 medium. The cells were grown at 37° C in a water-bath shaker and their growth followed spectrophotometrically at 660 mμ. Table 1 lists the growth rates for the cells in each medium.

All vegetative cells were collected in the log phase of growth. Spores were grown and purified as described previously[2]. The RNA from the cells and spores was purified by the phenol method[3]. To determine the ratio of soluble RNA to ribosomal RNA, the bulk RNA from individual cultures was fractionated by a methylated albumin column[4]. The RNA was eluted from the column with a linear sodium chloride gradient from 0·3 to 1·2 M. A clear separation of the two types of RNA was obtained as illustrated in Fig. 1. The total amount of soluble and ribosomal RNA from each culture was obtained by summing the optical density readings at 260 mμ of the soluble RNA peak (labelled 4*s*) and the ribosomal RNA peaks (labelled 16*s* and 23*s*). The percentage soluble RNA was determined by dividing the total optical density of the soluble RNA peak by the total optical density of both the soluble and ribosomal RNA peaks.

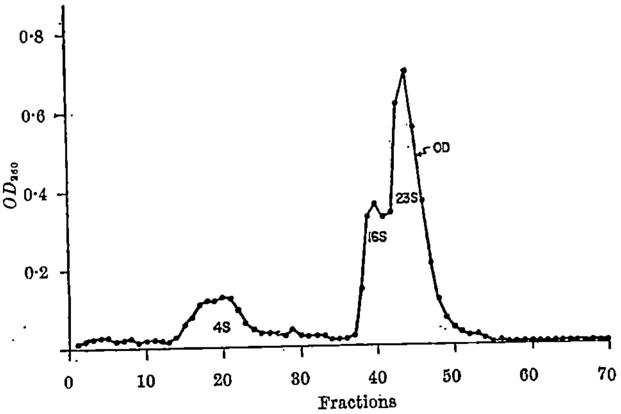

Fig. 1. Methylated albumin column fractionation of bulk *B. subtilis* RNA. The 4*s* peak is soluble RNA; the 16*s* and 23*s* peaks represent ribosomal RNA

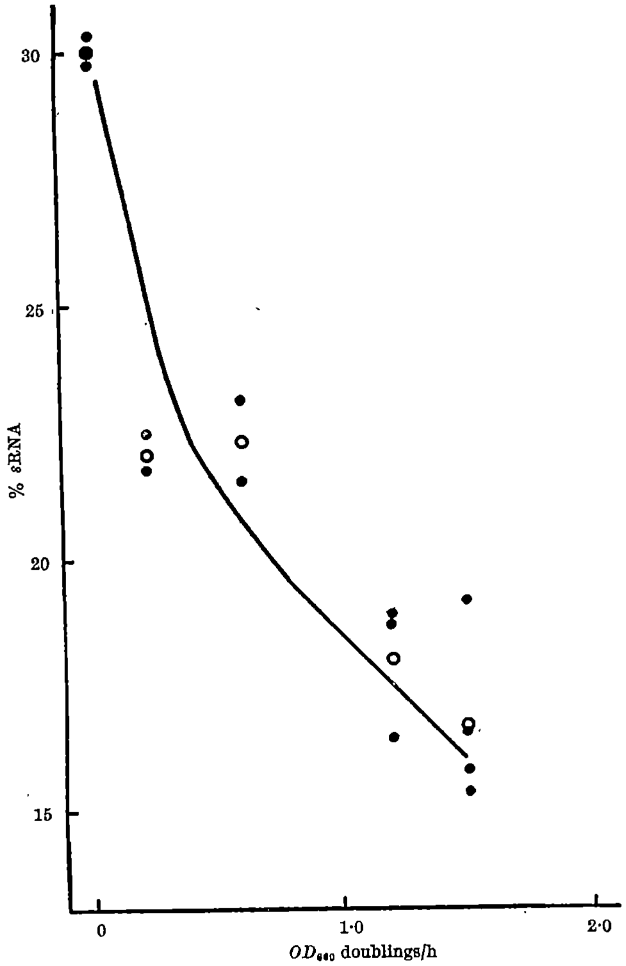

Fig. 2. The ratio of soluble RNA to total RNA at various growth rates. The closed circles represent individual experiments. The open circles represent the average values of the various experiments at a given growth rate

Table 1. GROWTH RATE OF *Bacillus subtilis* IN VARIOUS MEDIA

Medium	Growth rate (OD_{660} doublings/h)
'Penassay' broth	1·50
SCM-1*	1·20
SCM-2*	0·60
SCM-3*	0·22

* See text for description of media.

Fig. 2 indicates the relationship found between growth rate and the ratio of soluble RNA to ribosomal RNA at each of the growth rates listed in Table 1. Each point in the figure represents an independent experiment in which the RNA from cells grown at a specific growth rate was fractionated by column chromatography into the soluble and ribosomal RNA fractions. The results indicate that the ratio of soluble RNA to ribosomal RNA increases with decreasing growth rates. The spore which has a growth rate of 0 has the highest ratio of soluble RNA to ribosomal RNA; the ratio of soluble RNA to ribosomal RNA in spores is twice that found at the highest growth rate examined. When the cells in the stationary phase preceding sporangia formation were analysed, it was found that they contained 26·4 per cent soluble RNA. Since it is difficult to measure growth during the stationary phase, these results were omitted from Fig. 2; however, if the average growth rate is very near to 0, then the ratio between soluble RNA and ribosomal RNA follows the relationship illustrated in Fig. 2.

The transition of the ratio of the two RNA fractions at different growth phases is indicated in Table 2. Cells grown in 'Penassay' broth were examined during the log and stationary phases and as spores. The cells in the stationary phase were obtained 3 h before the appearance of sporangia. The increase in the relative amount of soluble RNA is clearly discernible.

Table 2. RIBONUCLEIC ACID COMPOSITION DURING DIFFERENT GROWTH PHASES OF *Bacillus subtilis*

Growth phase	% soluble RNA	% ribosomal RNA
Log phase	16·6 ± 1·2	83·4 ± 1·2
Stationary phase	26·5 ± 0·5	73·5 ± 0·5
Spore	30·0 ± 0·3	70·0 ± 0·3

These results support the finding of Kjeldgaard and Kurland[1] in terms of the relationship of RNA composition and growth rate. Although they found that soluble RNA could comprise 60 per cent of the total RNA of *Salmonella typhimurium* at low growth rates (0·2 doublings/h), we found a maximum of about 25 per cent at 0·22 doublings/h; it therefore appears that interspecies differences do occur. However, the results do support the expectation that bacterial spores contain the highest soluble RNA to ribosomal RNA ratio.

Furthermore, the results show that there is an increase in the soluble RNA to ribosomal RNA during the stationary phase accompanied by decreased synthetic activity. The ultimate level of soluble RNA is reached then in spores which are completely dormant. Although very little is known about sporangial metabolic activity, it would appear from the conclusions of Kjeldgaard and Kurland[1] and our results that protein synthesis within the sporangium is occurring at a very low rate. Therefore, differentiation into spores may be triggered by events which lead to the over-all decrease in rate of protein synthesis.

GENETICS

Transferrin Variation in Kangaroos

Inherited variation in the electrophoretic mobility of the serum protein transferrin (siderophilin) has been established for a number of mammalian species[1–12] and for doves[13]. In other mammals[14,15], several colubrid snakes and one amphibian species, variants exist[16] and, although family data are not yet available, it is probable that they are also genetically determined. This communication reports the discovery of inherited variation in the transferrin of an Australian marsupial, *Megaleia rufa* (=*Macropus rufus*), commonly known as the red kangaroo.

Samples of serum or, in a few cases, heparinized plasma were subjected to electrophoresis in starch-gels under essentially the same conditions as those described by Smithies[17], with the exception that platinum electrodes were used at both terminals in a solution of 0·75 M boric acid and 0·125 sodium hydroxide. To several runs, 2–5 μc. iron-59 as ferric citrate were added to the serum. An autoradiograph was made by placing one-half of the gel in a thin sealed polyvinyl chloride bag and leaving it in contact with a 'Kodirex No-Screen' X-ray plate at – 30° C for 24–36 h. The other half was stained with amido black 10*B* (Gurr). Two transferrin patterns were observed. The first type possesses three iron-binding bands, the second four; in both types the fastest and slowest bands are very faint.

The family data are shown in Table 1. Some of them are in the form of mother–offspring combinations. The certainty with which one can ascribe the parentage of a young marsupial to the female in whose pouch it is found should be further exploited in the genetical investigation of this and other marsupial species. It is proposed that the difference between the two types is controlled by a single gene pair, Tf^1 and Tf^2. The first pattern is that of the homozygote $\mathrm{Tf}^1\ \mathrm{Tf}^1$, the second that of the heterozygote $\mathrm{Tf}^1\ \mathrm{Tf}^2$. Each allele determines three bands in a starch gel. The heterozygote on this basis possesses six kinds of transferrin, two pairs of which have identical mobilities in the electrophoretic system employed here. The expected phenotype of the postulated $\mathrm{Tf}^2\ \mathrm{Tf}^2$ homozygote is shown in Fig. 1. Attempts are being made to produce an animal of this genotype by mating captive heterozygous animals. The failure to discover it so far is attributable to its low frequency in the two series examined.

One sample, of 22 individuals, was from a very restricted area on Mount Murchison station near Wilcannia, New South Wales, and had a frequency of $\mathrm{Tf}^2 = 0{\cdot}04$ (95 per cent confidence limits = 0·01 – 0·18).

Table 1. Family Data on Transferrin Variation in the Red Kangaroo

Parents		Offspring	
Female	Male	$\mathrm{Tf}^1\ \mathrm{Tf}^1$	$\mathrm{Tf}^1\ \mathrm{Tf}^2$
$\mathrm{Tf}^1\ \mathrm{Tf}^1$	?	7	0
$\mathrm{Tf}^1\ \mathrm{Tf}^2$	?	2	1
$\mathrm{Tf}^1\ \mathrm{Tf}^2$	$\mathrm{Tf}^1\ \mathrm{Tf}^1$	0	1
$\mathrm{Tf}^1\ \mathrm{Tf}^1$	$\mathrm{Tf}^1\ \mathrm{Tf}^2$	1	1
$\mathrm{Tf}^1\ \mathrm{Tf}^1$	$\mathrm{Tf}^1\ \mathrm{Tf}^1$	9	0

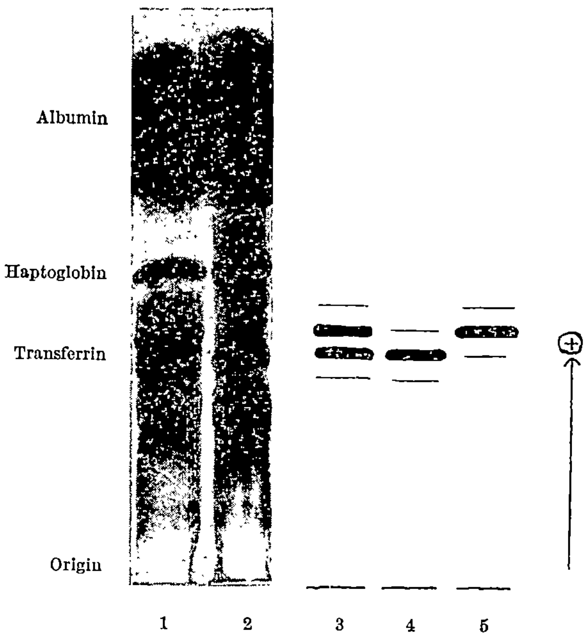

Fig. 1. 1, 2, Starch gel stained with amido black showing transferrin variants in the red kangaroo. 3, 4, Diagram of autoradiograph showing positions of iron-binding bands in 1 and 2 respectively. 5, Expected pattern of the iron-binding bands in the postulated $\mathrm{Tf}^2\ \mathrm{Tf}^2$ homozygote

A series of 34 individuals kept in captivity at the C.S.I.R.O. Division of Wildlife Research, Canberra, also had a frequency of $\mathrm{Tf}^2 = 0{\cdot}04$ (95 per cent confidence limits = 0·004 – 0·11). These came from various widely separated areas of New South Wales and South Australia; in some cases, the point of capture was unknown. Data from the offspring of these animals are included in Table 1.

In the calculation of gene frequencies and confidence limits Cotterman's method of weighting[18] has been used to allow for the inclusion of related individuals. The 95 per cent confidence limits have been obtained using Steven's "Table for the Limits of the Expectation for Binomial and Poisson Distributions"[19].

We thank Dr. H. J. Frith, chief of the C.S.I.R.O. Division of Wildlife Research, for the collection of the Wilcannia samples and Mr. R. Goodwins of the University of Adelaide for preparation of Fig. 1.

ABO Blood Groups in Sarcoidosis

The distribution of the ABO blood groups is interpreted by Vogel (1961) as the outcome of a dynamic equilibrium between the selective action of epidemic diseases of the world-populations and selection through materno-fœtal incompatibility.

The methods were described at the first and especially at the second International Congress of Human Genetics. The results were reported of investigations being conducted on the association of the ABO blood groups with the varial diseases. Our own investigations regarding the ABO blood groups in sarcoidosis are based on a sample of 518 patients suffering from these diseases.

Table 1. Relative Incidence of ABO Blood Groups in Sarcoidosis and Tuberculosis

	No. of sample control	No.		Comparison	Relative incidence Type A	χ^2 ($m=1$)	P Probability	P Heterogeneity
		Patients	Controls					
Sarcoidosis	1	518	81,985	A : O	1·142	15·22	0·0001	—
Tuberculosis	10	4,505	19,883	A : O	1·1360	12·19	0·0005	0·06

The complete material for ABO blood groups is presented in Table 1. The distribution of ABO blood groups in patients affected with sarcoidosis is compared with the distribution of ABO blood groups in the Federal Republic of Germany. These statistically significant results demonstrate that the relative incidence of type A is 1·142 as against 1 in type O. It means that persons with the blood group A had a 14·2 per cent more frequent probability to acquire a sarcoidosis than persons with the blood group O.

In this connexion it is very interesting that in basal tuberculosis, too, a small preponderance of the blood group A exists. In a second investigation we were able to evaluate the data in 10 samples of former scientific publications. But we could not find a relation of sarcoidosis with the rhesus blood groups and the serum haptoglobins.

So it seems that the gene of the blood group A in the multifactorial genetic systems of sarcoidosis is of some importance.

Mutant Expression and Canalization

Experiments in which mutant expression was altered by selection have shown that changes in expression are more easily brought about over some parts of the range than others[1-4].

Explanation of this phenomenon, which was interpreted as a consequence of the canalization of normal development, implied that the developmental system governing the expression of the character has at least two components.

One component is sometimes represented as a morphogenetic substance[4,5]. Change of concentration of this hypothetical substance (by environmental factors or selection on expression) would cause a change in mutant expression. The amount of this substance is supposed to vary in different members of a population in a regular and continuous manner. The differences in sensitivity to change (canalization) of expression at different levels of expression, which sometimes result in irregular frequency distributions of the phenotypes[1,4], are a consequence of a second component.

This second component relates the amount of the morphogenetic substance in an individual to the phenotypic expression of the mutant in that individual. The genetic basis of this component must be—at least in part—independent of the genetic basis of the first component[4]. This second component would cause characteristic response curves relating factors which change expression with the magnitude of change in expression. It has been supposed that the mutants involved in the investigations quoted here cause only a decrease in the amount of morphogenetic substance and do not affect the response curve.

I have found[4] that in the mutant *cubitus interruptus* dominant (ci^D) of *Drosophila* genetic differences, differences in environment (temperature) and also differences operating within flies, all act according to the same characteristic response curve. If ci^D affects only the level of the morphogenetic substance, then the response curve for ci^D expression would represent the response curve of the developmental pathway to a normal longitudinal wing vein (canalization cross-section[6]). But neither these experiments nor similar experiments with other mutants could prove that the mutant had no effect on the response curve[4,7].

If the response curve of ci^D represents the canalization cross-section of fourth vein development in the normal fly, one should expect that similar curves can be obtained with certain other mutants which cause a terminal interruption of the fourth vein.

Therefore, two other mutants were tested in temperature experiments, namely, ci^{D-G} (*cubitus interruptus* dominant of Gloor, 4–0·00) and H (Hairless, 3–69·5; in a stock selected for complete penetrance of fourth vein expression).

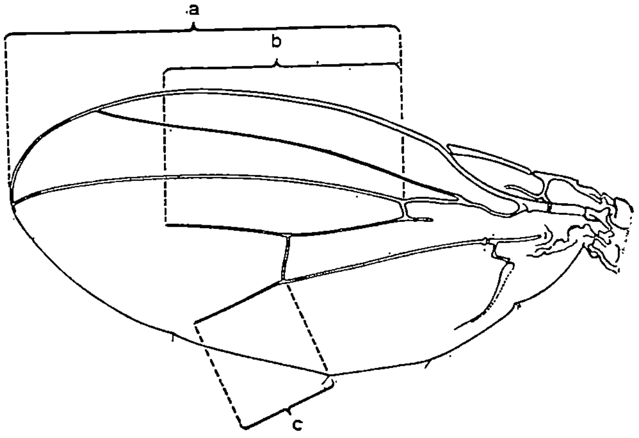

Fig. 1. Measurement of expression on a ci^D-wing. Expression of the 4th vein interruption was measured as the percentage ratio of the length of the 4th vein (*b*) to the length of the 3rd vein (*a*). Expression of the 5th vein interruption as the ratio of the 5th (*c*) and the 3rd vein (*a*)

The expression was measured as indicated in Fig. 1. At each temperature four vial cultures were reared each stocked with 70 larvæ. From each culture 20 females were measured.

The resulting response curves are given in Fig. 2 along with curves obtained earlier for two ci^D stocks with different expressions[4].

The response curves both of ci^{D-G} and H differ basically from the ci^D curves. In ci^{D-G} response is almost linear over the whole expression range. There is no indication of a region of non-linearity around the 70 value which is characteristic for ci^D (ref. 4). Furthermore, there is no indication that on approaching wild-type in expression, further response is becoming more difficult.

In the case of H, change of expression is even facilitated as wild-type is approached.

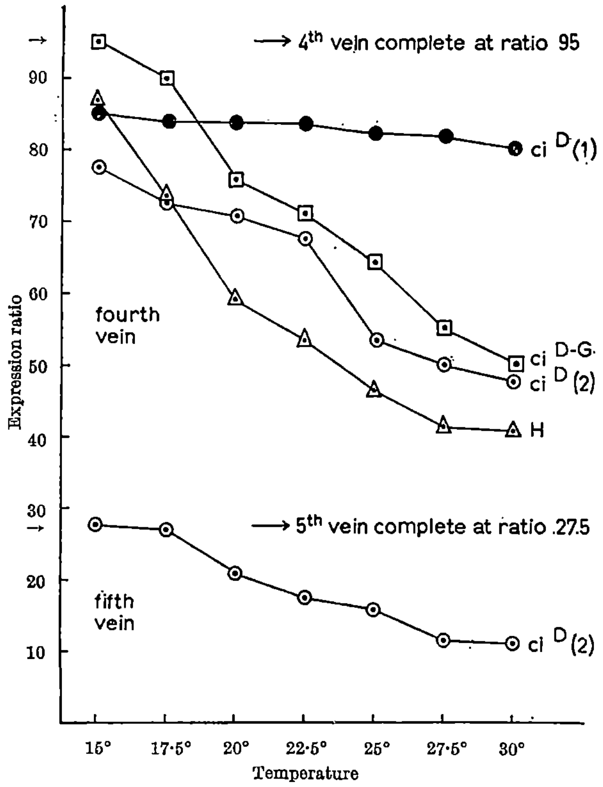

Fig. 2. Relation between temperature and expression (measured on the 4th longitudinal wing vein) of the mutants ci^{D} (2 stocks with different expression ratios), ci$^{D\text{-}G}$, and H. From one ci^{D} stock also expression on the 5th vein is given

Obviously, then, the shape of the response curve of this character (terminal gap in the fourth vein) is dependent on the mutant used in the experiments.

One could reason that nevertheless, in certain cases, as, for example, in ci^{D}, the response curve coincides with the canalization cross-section and that in other mutants, as, for example, in H, the response curve alone is altered, instead of the amount of morphogenetic substance. In the latter case an occasional fourth vein interruption occurring when Hairless is introduced in wild genotypes could be explained by weakening of canalization. Reduced efficiency of canalization would then allow for a certain amount of phenotypic expression of the normal variation in morphogenetic substance, while the same variation in wild-type cannot reach a threshold value set by normal canalization.

The characteristic bimodal frequency distribution of the expression of the mutant deformed recessive of Lüers with modes at either side of wild-type[8], and other cases of 'polar variation'[9] of mutant expression in *Drosophila*, can perhaps be explained in this way.

However, the realization of a morphological character involves a sequence of different processes or, more precisely, a variety of interconnected sequences. It then seems too simple a view to expect that every process in such a sequence, not to mention processes in different sequences, would show the same response curve for sensitivity to environmental and genetic factors. It must be expected that the canalization cross-section of a character could be different at different stages in the realization of the character. The response curves of the three mutants tested in these experiments might therefore represent the canalization cross-section of the fourth vein formation at different times in development.

This suggestion finds support in the fact that the temperature sensitive periods (T.S.P.) for the three mutants are different. While the T.S.P. for ci^{D} starts later than 4 h after pupation, the same period in H begins before pupation and ends before the beginning of the ci^{D} period. The T.S.P. for ci$^{D\text{-}G}$ overlaps with both the period of H and ci^{D} (refs. 10 and 11).

Evidence suggesting that the response curves of the mutants represent the response curve of a process in normal development comes from selection experiments with H and ci^{D}.

Long-term selection for extreme expression of ci^{D} (40–50 generations) did not accumulate a system of modifiers which had an effect on the fourth vein development independent of the presence of the ci^{D} mutant[4,12]. On the other hand, selection on Hairless fourth vein expression (in populations segregating for H and wild-type individuals) showed a rather surprising result. After a few generations of selection, some of the non-Hairless segregants already showed a fourth vein interruption.

It is tempting to relate this easy 'assimilation' of the Hairless fourth vein interruption with the shape of the temperature response curve of this mutant. This curve indicates that change of expression in the neighbourhood of the normal phenotype is relatively easy, while in the case of ci^{D} the opposite is true. Preliminary evidence is available which indicates that also in Hairless genetic factors act according to the same response curve as temperature.

As mentioned before, long-term selection on ci^{D} fourth vein expression did not lead to a break of the fourth vein in individuals without the mutant. But in one line the gap on the fifth vein (which is a regular pleiotropic effect in standard ci^{D}) was increased by selection for increased fourth vein. In this line then, the fifth vein gap appeared independently of the presence of ci^{D} and was shown to be determined polygenically[12].

Now the response curve of the fifth vein break in ci^{D} does not show any indication of canalization (Fig. 2). This, too, points to a relation between the shape of the response curve of a mutant character and the ease of assimilation. The sensitivity to assimilation, of course, is an indication of sensitivity of the pertinent developmental process in normal development.

In this train of thought an essential element is the assumption that at least part of the modifying genes are specifically acting on the sensitive point in the development of the mutant that is revealed by its temperature sensitive period[13]. If this assumption is correct, modifying genes acting on the expression of a given character (for example, fourth vein gap) in different mutants (for example, ci^{D} and H) should be at least partly different.

That such a specificity of modifiers does indeed exist is indicated in the case of ci^{D} and H, where preliminary evidence is available that the modifying genes of ci^{D} have only little effect on the expression of H, and vice versa.

This research was started during tenure of a NATO science fellowship awarded to me by the Netherlands Organization for the Advancement of Pure Research. I thank Prof. C. H. Waddington (Edinburgh) for hospitality in his Institute and for his advice. I also thank Prof. H. J. Gloor (Leiden) and Dr. J. Maynard Smith (London) for advice concerning the manuscript.

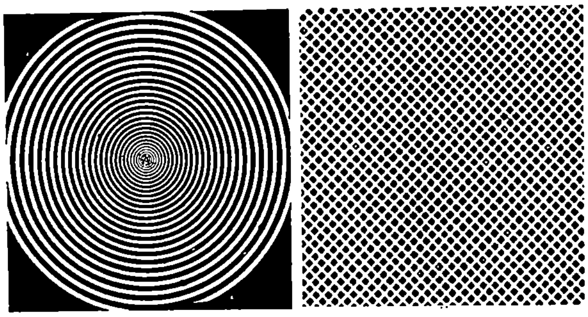
PSYCHOLOGY

Dynamic Distortions of Perceived Form

It is becoming increasingly clear that the visual perception of form involves the interaction of a number of parallel computing or 'image-processing' operations. Stimuli which preferentially excite one or other of the neural computing networks concerned can give rise to visual anomalies indicative of the way in which the optical information is normally broken down.

I have recently observed a striking anomaly in this class. When two regular patterns such as Figs. 1*a* and *b* are superimposed, they form the 'Moiré pattern' of Fig. 2. If now the second is moved relative to the first, say along the vertical axis of the figure, the lobes of Fig. 2 undergo a continual displacement in the general direction of the arrows, and so long as motion persists the form seen presents an asymmetrical appearance. As soon as motion ceases, however, symmetry returns, the lobes appearing to 'snap back' in a fraction of a second to their positions in Fig. 2. The transition from dynamic to static form is sufficiently striking to evoke incredulity in some subjects. Since the static form is seldom exactly symmetrical, it is necessary (and proves convincing) to control for residual asymmetry by arranging that the figure returns to exactly the same rest-position from opposite directions alternately.

The problem here is that identical figures of excitation on the same retinal area lead successively to different perceptions of form. In general terms the explanation is obvious, that the form seen under dynamic conditions is some kind of running average over the moving figures presented; but since this 'average' is as sharp as the static form, and since it is asymmetrical, it must be computed from a logically dissected representation of the stimulus, in which the velocity-components of the retinal image can apparently contribute to the computation of contour position. With translation of a rigid figure, this 'abstract averaging' need give rise to no anomalies of form perception, though it may be responsible for some illusions of displacement[1]. When, however, the figure is a Moiré pattern the components of which have a different 'phase velocity' from the velocity of the group as a whole, the contributions from contour velocity can grossly bias the perceptual estimate.



a *b*

Fig. 1

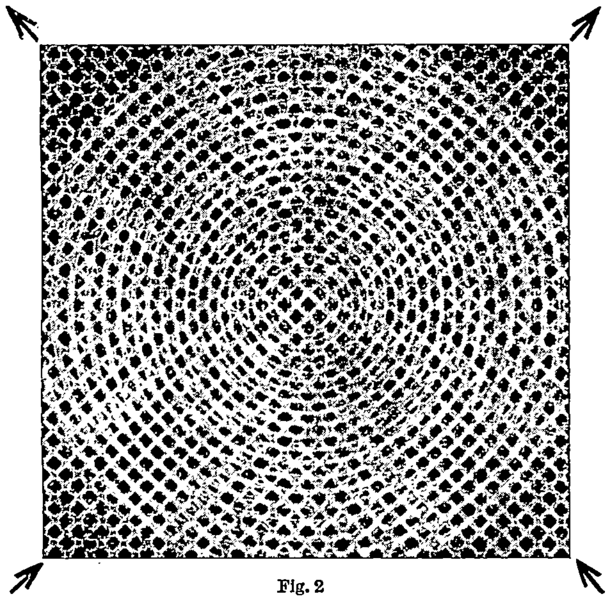


Fig. 2

The phenomenon seems to be in line with other recent evidence[2–4] suggesting that different neural networks are concerned with the signalling of contour direction, contour velocity and contour location.

STATISTICS

Some Properties of Random Variables

In text-books on probability the following (perhaps curious) properties of random variables do not appear to have been noticed so far.

Consider a bi-variate distribution (Z, U) where both Z and U are positive finite random variables. There will be occasion to refer to Z as the numerator variate. Then one property of positive random variables is that:

$$\mathrm{Cov}\left(U, \frac{Z}{U}\right) \leqq V(\sqrt{Z}) \qquad (1)$$

To prove this inequality we have, by definition:

$$\mathrm{Cov}\left(U, \frac{Z}{U}\right) = E(Z) - E(U)\, E\left(\frac{Z}{U}\right) \qquad (2)$$

Applying Cauchy's inequality, we find:

$$E(U)\, E\left(\frac{Z}{U}\right) \geqq \left[E\left(\sqrt{U}\sqrt{\frac{Z}{U}}\right)\right]^2 \qquad (3)$$

or

$$E(U)\, E\left(\frac{Z}{U}\right) \geqq [E(\sqrt{Z})]^2 \qquad (3{\cdot}1)$$

In equation (3), equality is attained if, and only if, $\sqrt{\frac{Z}{U}}/\sqrt{U}$ is equal to a constant, say $\sqrt{c}$, for all pairs (Z, U), leading to the condition

$$Z = cU^2 \qquad (4)$$

On multiplying each side of (3·1) by -1 and reversing the sign of inequality, and then adding $E(Z)$ to each side, the result given by equation (1) will be obtained. When equation (4) holds, $\mathrm{Cov}\,(U, cU) = V(\sqrt{c}\,U) = cV(U)$, an identity which is to be expected.

Another property of positive random variables is that the correlation with their respective reciprocals, that is, $\rho\left[U, \frac{1}{U}\right] \leqq 0$. The proof of this proposition follows from equations (2) and (3·1) by putting $Z = 1$. Condition equation (4) shows that this correlation is zero only when all the U's are equal.

An interesting question arises as to what is the analogue of the result given by equation (1), when the signs of all the numerator variates are reversed, that is, they now assume finite negative values while their corresponding U's remain positive as before. The probabilities for each pair remain unchanged. In this situation let $(-1)Z = z$, where Z is positive. Thus the variate value of $\sqrt{z} = \sqrt{-1}\sqrt{Z}$ will be a complex number without a real part, and since this circumstance rules out the use of Cauchy's inequality, we adopt the following stratagem to establish the analogous proposition. If the sign of each z is reversed, then obviously equation (1) can be applied. Now multiplying each side of this inequality by -1 we find:

$$-\mathrm{Cov}\left[U, \frac{Z}{U}\right] \geqq (\sqrt{-1})^2 V(\sqrt{Z}) \qquad (5)$$

In equation (5), as it stands, by factoring the coefficient -1 into the covariance function as a coefficient of Z, and $(\sqrt{-1})^2$ into the variance function as a coefficient of $\sqrt{Z}$, we obtain:

$$\mathrm{Cov}\left[U, \frac{z}{U}\right] \geqq V(\sqrt{z}) \qquad (6)$$

in view of the relation $z = -Z$. It is interesting to note that equation (1) has served as a scaffolding for the derivation of equation (6), where equality is attained if, and only if, $-z = cU^2$.

A statistically meaningful interpretation of the inequality equation (6) hinges on the interpretation of the lower bound of its covariance function, namely:

$$V(\sqrt{z}) = V(\sqrt{-1}\sqrt{Z}) = -V(\sqrt{Z}) \qquad (7)$$

That is, the variance of the complex variates $\sqrt{z}$, or let us say the abstract variance of the $\sqrt{z}$'s, is equal to the variance of the square root of their corresponding real variates multiplied by -1.

The last property of random variables as manifested by equation (6) may throw some light on the nature of the underlying variables in linear models used in the analysis of variance in circumstances when their estimates of variance are negative. It is hoped to investigate this question.

A Probabilistic Similarity Index

Williams *et al.*[1] have recently proposed that, for similarity indices used for numerical taxonomy, each attribute should be weighted according to the sum of the χ^2 values obtained from 2 × 2 tables testing the association of this attribute with all others. This relates the measure of similarity to the distance separating the two individuals in a multi-dimensional space where each axis representing an attribute has a scale depending on the importance of that attribute. Though based on χ^2 calculations, the index is not considered to be probabilistic, though the authors adumbrate the possibility of developing probabilistic methods of similarity analysis.

A similarity index based directly on probability theory is in use in this laboratory, which takes full account of ordered and quantitative attributes as well as of those which in their nature are binary. For each pair of individuals in a sample or population, the exact probability is computed for each attribute in turn that a random sample of two will resemble one another not less closely than the two under test. In computing this probability, the null hypothesis is that the two individuals in question are part of the same population as the rest, while the alternative hypothesis is that these two are a sample from another population.

The phrase "resemble one another not less closely" clearly calls for definition; the appropriate definition varies with the type of attribute.

For purely qualitative attributes, those concordances supporting the alternative hypothesis against the null hypothesis which are less probable under the latter are taken to be evidence of closer resemblance (or better evidence of resemblance). Thus, if an attribute can take three values x_1, x_2, and x_3, and the probabilities that, for any particular individual, the attribute will take these values are respectively 0·1, 0·3 and 0·6, agreement in having the first value would be considered better evidence of resemblance than agreement in having the second or third.

For ordered (but non-metrical) attributes, the degree of resemblance is taken as a function of the proportion of individuals in the same classes as the two under test, or in any intermediate class. Thus, if five ordered classes contain the following proportions of the population: 0·1, 0·2, 0·1, 0·4, 0·2, two individuals in the first and third classes are taken as being more similar than two in the fourth and fifth. For metrical attributes, the range is taken as a criterion of similarity, so that two individuals differing by less in the numerical values of this attribute are regarded as more similar than another pair in which the numerical values are more widely separated. A logarithmic scale might, of course, be used where appropriate.

The probability of the observed, or any closer, degree of resemblance having been computed for each attribute, the problem then remains of combining these probabilities, on the assumption of their independence. Where the probabilities arise from a continuous distribution, the solution has been given by Fisher[2]. He computed:

$$-2\sum_{i=1}^{n} \ln p_i$$

and showed that this quantity was a χ^2 variate with $2n$ degrees of freedom. For most types of attributes, this provides an acceptable approximation to the true multinomial distribution. An exception is formed by binary attributes—the most common type—for which the probability of the observed degree of resemblance between the two individuals is limited to three values. Here, Fisher's continuous solution may lead to a large positive bias, and the method adopted instead has been to combine these probabilities in small groups by the exact multinomial method (to apply it to any large number of attributes would be computationally impracticable), and then combine these group probabilities, now quasi-continuous, by Fisher's method.

When this has been done, the resulting combined probability P_t provides a satisfactory index of dissimilarity, and its complement $(1 - P_t)$ is an index of similarity ranging (like those commonly used) from zero when the two individuals are completely dissimilar to near unity when they are closely similar. Unity can be attained only when the population on which the probability estimates are based is infinite.

The whole procedure outlined in this paper has been programmed in *Fortran II* for the IBM 1620_3 computer, and copies of the programme are available to enquirers. A full account of the technique is being prepared for publication.

I thank Mr. D. W. G. Moore, officer in charge of the Computing Centre of the University of Western Australia, for the facilities used in this work.

FORTHCOMING EVENTS

Friday, September 11

F. and M. Scientific Europa N.V. (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 7 p.m.—Dr. Charles C. Sweeley (University of Pittsburgh): "Advances in Gas Chromatography Techniques Applied to the Analyses of Carbohydrates and Related Polyhydroxy Compounds".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Demonstrator (with B.Sc. honours degree in geography and a special interest in cartography and surveying) in the Department of Geography—The Registrar, The University, Nottingham (September 10).

Lecturer in Mathematics; a Lecturer in Statistics; a Senior Lecturer in Biochemistry; a Senior Lecturer in Civil Engineering; and an Assistant Lecturer (Grade B) in Mechanical Engineering—The Principal, Nottingham and District Technical College, Burton Street, Nottingham (September 10).

Lecturer in Organic Chemistry; a Lecturer in Inorganic and Physical Chemistry; an Assistant Lecturer (Grade "B") in Inorganic and Physical Chemistry; and an Assistant Lecturer (Grade "A") in General Chemistry at Birkenhead Technical College—The Director of Education, Birkenhead Education Committee, Education Offices, 63 Hamilton Square, Birkenhead (September 14).

Lecturer (preferably with a special interest in medical statistics) in the Department of Statistics—The Secretary, The University, Aberdeen (September 14).

Lecturer or Assistant Lecturer (preferably with experience or special interest in one or more of the following fields: production engineering, nuclear engineering, thermodynamics and mechanics of fluids, and preferably an interest in design) in Mechanical Engineering—The Registrar, The University, Leeds, 2 (September 14).

Senior Lecturer (well qualified academically and considerable experience in teaching and/or industry and/or research) in Physics or Applied Physics—The Secretary, Welsh College of Advanced Technology, Cathay's Park, Cardiff (September 14).

Lecturer (preferably with a good honours degree in geography) in the Department of Geography, University of Ghana, to teach biogeography or climatology as well as the regional geography of North America, Europe or Asia—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1 (September 15).

Research Fellow (specializing in water chemistry and bacteriology) to undertake research work on the waters of the developing Volta Lake (University of Ghana, Volta Basin Research Project)—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1 (September 15).

Science Librarian (professionally qualified graduate or Fellow of the Library Association, and experience in a special library or in the science section of a university library) in the Balme Library, University of Ghana—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1 (September 15).

Assistant Lecturers (2) (candidates for the one post should have special interests in the evolutionary field studies, and for the other in physiology) in Zoology—The Registrar, The University, Manchester, 13 (September 18).

Research Associate or Senior Research Associate (with an honours degree in engineering and some experience in research in the field of structures, or alternatively experience in the analysis and design of structures) in Engineering (Civil), for work on the application of computer methods to structural analysis and design—The Registrar, The University, Manchester, 13 (September 18).

College Lecturer (with an honours degree in agricultural chemistry, chemistry or biochemistry, with postgraduate experience in soil chemistry, plant biochemistry or other related field) in the Soils Division, Department of Agricultural Chemistry and Soil Science—The Professor of Agricultural Chemistry, University College, Glasnevin, Dublin, Republic of Ireland (September 19).

Newton Drew Chair of Fuel Technology and Chemical Engineering—The Registrar, The University, Sheffield, 10 (September 19).

Lecturer (with experience either in reaction mechanisms or in the application of infra-red spectroscopy) in Organic Chemistry; an Assistant Lecturer (with experience in instrumental and general analysis) in Analytical Chemistry; and a Research Fellow for work involving investigations into polymer technology—The Assistant Registrar (Science), The University of Birmingham, Birmingham, 15 (September 21).

Graduate (with a strong background in physical chemistry) in the Department of Chemistry, to engage on research on nuclear magnetic resonance of simple nitrogen-15 compounds of biological importance—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (September 25).

Lecturer in the Department of Psychiatry—The Registrar, The University, Leeds, 2 (September 26).

Reader in Microbial Genetics—The Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne (September 26).

Assistant Lecturer (Demonstrator) in the Department of Anatomy (Prof. J. Z. Young), to undertake teaching and research—The Secretary, University College, Gower Street, London, W.C.1 (September 30).

Chair of Applied Mathematics—The Registrar, The University, Manchester, 13 (September 30).

Chair of Electrical Engineering at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

Senior Lecturer or Lecturer in Cytogenetics and Taxonomy (including the development of the Herbarium) in the Department of Botany, University of Ife, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (September 30).

Senior Lecturer, Lecturer or Assistant Lecturer in Botany, Mathematics, Physics (2 posts), the Department of Education, and the Institute of Education, University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (September 30).

Plant Physiologist (with a good degree or equivalent in biology, botany or horticulture and an interest in physics, and preferably some research experience), for work on the use of CO_2, water and energy by glasshouse crops—The Secretary, N.I.A.E., Wrest Park, Silsoe, Bedford (October 1).

Research Assistant in the Department of Chemistry to work on the isolation of the glucose transport system from red blood cells—The Registrar, The University, Manchester, 13 (October 1).

Lecturer/Senior Lecturer in Biometry; and a Lecturer/Senior Lecturer (with special interests in either the physical aspects of geography and, in particular, specific qualifications in climatology or in economic geography and quantitative methods) in Geography at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 5).

Research Fellow (biochemist or physical chemist) in the Department of Microbiology, John Curtin School of Medical Research, Institute of Advanced Studies, Australian National University, to work on the nucleic acids of animal cells and animal viruses—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 12).

Chair of Mechanical Engineering in the Faculty of Engineering, University of Malaya, Kuala Lumpur—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, October 15).

Lecturer in Geophysics at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 15).

Research Fellow (graduate with experience in immunology) in the Hugh Adam Department of Cancer Research, University of Otago—The Registrar, University of Otago, P.O. Box 56, Dunedin, New Zealand (October 15).

Lecturer in the Department of Mechanical Engineering, University of Cape Town—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (London and Cape Town, October 19).

Chair of Veterinary Surgery at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 23).

Lecturer or Assistant Lecturer (with a degree in electrical engineering, and an interest or postgraduate experience in the field of electronics, preferably microwaves or semi-conductors) in the Department of Electrical Engineering, University of Melbourne, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 24).

Professor of Organic Chemistry—The Registrar (Room 22, O.R.B.), The University, Reading (October 24).

Chair of Pathology at the University of Tasmania, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 30).

Director (with an honours degree in forestry or its equivalent, considerable experience of research in several branches of forestry, administrative experience, a sound knowledge of two or more modern languages, preferably including German, ability to write good concise English, and preferably editorial experience) of the Commonwealth Forestry Bureau, Oxford—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (October 31).

Post-doctoral Fellows (2) (physical chemists or physicists) to carry out research on atomic reactions—The Registrar, University of Canterbury, Private Bag, Christchurch, New Zealand (November 30).

Biochemist (interested in studying for a higher degree, and preferably with some enzymological experience) for work on isoenzyme purification and properties—Prof. D. N. Baron, Department of Chemical Pathology, Royal Free Hospital, Gray's Inn Road, London, W.C.1.

Demonstrator (Nigerian, with a good first degree in physics), for duties which will include the preparation and testing of undergraduate experiments, laboratory supervision, and organization of tutorials—The Registrar, University of Ife, Ibadan Branch, Ibadan, Nigeria.

Entomologist (between 23–44 years, with a degree in botany, zoology or entomology, and relevant postgraduate experience in applied entomological research) in Northern Rhodesia, to carry out research into the life history and control of pests of agricultural and horticultural importance—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/132/03.

Entomologist (national of the United Kingdom or the Republic of Ireland, with a degree in biology and at least two years' postgraduate research) with the East African Common Services Organization, to study ways of improving methods of controlling or eradicating tsetse flies by insecticides and chemosterilants including both laboratory and field studies—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/214/07.

Head of the Electronics Shop in the New York Medical College, to be responsible for the design and maintenance of research and teaching equipment—Dr. V. B. Brooks, Professor of Physiology, New York Medical College, Fifth Avenue at 106th Street, New York, N.Y., U.S.A.

Lecturer in the Department of Organic Chemistry—The Registrar, The University, Liverpool, quoting Rev. CV/266/N.

Lecturer or Assistant Lecturer in Dairy and Food Technology with particular reference to quality control—The Registrar (Room 22, O.R.B.), The University, Reading.

Leukæmia Research Fellow (non-medical graduate with experience in cytogenetics) to study the cytogenetics of acute leukæmia in children—The Secretary, Institute of Child Health, Great Ormond Street, London, W.C.1.

Physicist (with a good honours degree in physics and preferably some experience in medical physics) to work jointly in the University Department of Medical Physics and the Hospital Department of Nuclear Medicine on problems associated with applications of radio-isotopes to clinical medicine—The Secretary to the Board, The General Infirmary, Leeds, 1.

Professor of Anatomy and Head of the Department—The Dean, Faculty of Medicine, University of Manitoba, Cor. Bannatyne and Emily Streets, Winnipeg, Manitoba, Canada.

Research Fellow or Senior Research Fellow (with a good honours degree in psychology and experience of research in experimental psychology or ergonomics) in Experimental Psychology/Ergonomics, to assist a team working on the effect of variations in job content and design on productivity—The Registrar, Bradford Institute of Technology, Bradford, 7.

Senior Research Assistant in Physics to work on electron spin resonance and relaxation in compounds which exhibit co-operative magnetism—The Registrar, The University, Sheffield.

Senior Technician (preferably with a special interest in microbiology) in the Applied Biology Department—The Registrar, Brighton Technical College, Richmond Terrace, Brighton, Sussex.

TECHNICIAN (with a knowledge of electronics) IN THE DEPARTMENT OF CLINICAL MEASUREMENT—The Secretary, Department of Clinical Measurement, Westminster Children's Hospital, Vincent Square, London, S.W.1.

UTILIZATION OF SCIENTIFIC AND ENGINEERING MAN-POWER

THE Committee on Utilization of Scientific and Engineering Manpower, of which Mr. J. R. Killian, jun., is chairman, was appointed in 1962 by the National Academy of Sciences and financed by a grant from the Ford Foundation. It has thus something of the status of the Committee on Scientific Man-power of the Advisory Council on Scientific Policy in Britain, and its report, *Towards Better Utilization of Scientific and Engineering Talent: a Program for Action**, has its place in a series of reports dealing with aspects of scientific and engineering man-power which have come from the President's Science Advisory Committee during the past two years. It does not deal with the problem of dissemination of information, which was considered in 1963 in the report from that Committee, *Science, Government and Information* (*Nature*, 202, 735; 1964), nor with the support of basic research in the universities, which was covered by a report from the National Academy of Sciences, *Federal Support of Basic Research in Institutions of Higher Learning*. Similarly, graduate training in engineering, mathematics and physical sciences is left to the report under that title from the President's Science Advisory Committee, and the questions of technicians will be dealt with in an impending report from the same Committee.

Nevertheless, as the title of the present report indicates, it is more concerned with action than the reports that have so far come from the Committee on Scientific Man-power, or even, on this subject, from the Advisory Council on Scientific Policy. It includes a brief and clearly presented survey of needs and resources, which is summarized on p. 1125 of this issue of *Nature*, along with the nine study papers which form Part 2 of the report. The bulk of the first part of the report is contained in three chapters, which discuss successively the functions and responsibilities, in respect of the utilization of scientific and engineering man-power, of the Federal Government, industry and the universities. It is with these, and the brief chapter on research, that we are here concerned; the conclusions and recommendations set forth are relevant to the position in Britain, both from the point of view of the expansion of higher education and from that of the reorganization of civil research.

First, as regards Federal Government responsibilities, it should be noted that although only 11 per cent of scientists and engineers engaged in research and development are employed by the Federal Government, 60 per cent of the expenditure on research and development comes from the Government, and 80 per cent of this is dispersed by the Department of Defence and the National Aeronautics and Space Administration. It is scarcely surprising, therefore, that the Committee should recommend that before the Government makes a decision to undertake a great technological programme, such as the lunar landing or the supersonic transport projects, it should make a careful assessment of the impact of the decision on the deployment and utilization of scientists and engineers. How this is to be done depends on the administrative structure generally, but it is worth emphasizing that, in Britain, this appears to have been done reasonably well by the Advisory Council for Scientific Policy. Any changes in the organization of civil science should not be allowed to impair the Council's effectiveness in this field.

In the United States, the Committee on Utilization of Scientific and Engineering Manpower recommends that a unit within the Executive Office of the President should be made responsible for stimulating and co-ordinating planning by Federal Departments and agencies with respect to scientific and engineering man-power. Its responsibilities would also include the promotion of research, inside and outside Government, likely to facilitate the solution of man-power problems, and the initiation of an integrated programme for continuing collection and analysis of information on scientific and engineering man-power. The Committee suggests that such a unit might be placed in the Office of Science and Technology. Besides this, however, it recommends firmly that each department with major scientific or engineering activities should make one of its highest officials responsible for improving the utilization of civilian scientists and engineers, whether employed directly, or by those whose work it finances. Specifically, it recommends that an official in the Department of Defence be given such responsibilities to improve the utilization of civilian scientists and engineers working on defence programmes within the Department and elsewhere.

Such an official should: (1) participate in Government-wide scientific and engineering man-power planning activities and bring to the attention of his colleagues the implications, in terms of man-power, of proposed new programmes; (2) assess the impact on man-power of cancellation, curtailment or alteration of major programmes; (3) analyse the influence of man-power practices and policies on the effectiveness with which scientific and engineering man-power is utilized; (4) provide for the collection and analysis of the necessary information. While it would seem possible that the new organization of the Ministry of Defence could go some way towards securing these objectives in Britain, how far they are consistent with the control at present exercised by the Treasury generally is another matter. Particularly in view of comments by the Estimates Committee on the staffing of the new Diplomatic Services, recommended by the Plowden Committee in its report on *Representational Services Overseas* (*Nature*, 203, 439, 797; 1964), the exercise of Treasury control might well be worth re-examining in the light of the comments in this report. Without such an enquiry, the appointment to major projects of outstanding managers with technical and administrative ability is unlikely to contribute greatly to the improvement of such management, nor are the managers likely to receive the necessary authority, responsibility and resources.

---

* *Towards Better Utilization of Scientific and Engineering Talent: a Program for Action*. Report of the Committee on Utilization of Scientific and Engineering Manpower. Publication No. 1191, National Academy of Sciences. (Printing and Publishing Offices, National Academy of Sciences, Washington, D.C., 1964.)

Here the wisdom of assessing these recommendations in the British context seems further emphasized by recent unhappy experience over the fixed-price contract system for guided weapons and the disclosures of the first report of the Inquiry into the Pricing of Ministry of Aviation Contracts, and the next few recommendations underline the same point. Government agencies responsible for developing programmes should continue to place emphasis on accurate estimates of their cost and feasibility, and on the use of multi-phase contracts. In development contracts the use of fixed-price and incentive contracts instead of cost-plus-fixed contracts is recommended. Moreover, Government agencies should take great care to establish meaningful and realistic criteria of performance. The Committee commends the increasing ability of Federal contracting agencies in the fields of defence and space to cancel, curtail or materially alter at an early stage major programmes that do not appear to be worth their cost. However, Federal departments and agencies should work with industry to develop plans and programmes for minimizing any dislocation or wastage of scientists and engineers as a result of such cancellation or redirection. They would also maintain Federal support of contractor-initiated technical programmes at a substantial level and develop incentives for encouraging corporate managements to emphasize quality and continuity, and to orient work towards long-term objectives.

The three last-mentioned recommendations relating to the Federal Government are concerned with its role as employer, and the Committee first recommends greater emphasis on assuring a high level of professional competence in the Federal scientific establishments. This is directed particularly at Congress, which should enact promptly the proposals of the administration for higher salaries at the upper levels in the Government Service. The Committee also recommends that the U.S. Civil Service Commission should take the initiative in improving the working environment of scientists and engineers employed by the Federal Government, and help to foster improved forecasting of their future requirements for scientific and engineering personnel. This recommendation is in line with the ideas of the Fabian Society's Committee regarding the functions of the Civil Service Commission as expressed in a recent report, *The Administrator: The Reform of the Civil Service* (*Nature*, 203, 555, 797; 1964). Finally, the Committee recommends periodic reviews by the Department of Defence, the Atomic Energy Commission, the National Aeronautics and Space Administration and other Government departments of the missions and the programmes of the research laboratories they finance, whether directly or under contract. This would ensure that their resources served national objectives of high priority, that arrangements for their management and location provide the maximum opportunity to be strong and creative, and that their programmes and administrative arrangements are compatible with the objectives of institutions with which they may be linked. In this, it is suggested, the resources of the President's Science Advisory Committee might be used.

Eight recommendations relate to the utilization of man-power by industry, and are concerned primarily with engineers and scientists engaged in research and development, and especially in the aircraft and missiles industry and in electrical equipment and communications. Together, these last-mentioned industries received 5,400 million out of the 6,700 million dollars which the Government spent in 1962 for research and development performed by private industry and accounted for 58 per cent of private and Federal investment in industrial research and development. The recommendations deal first with improving the management of research and with the key role of management. Corporate managers should identify their most promising scientists and engineers and take action to enable them fully to develop and apply their competence, and they should seek to provide a climate for creativity and productivity in keeping with the great potential of highly qualified scientists and engineers.

These have been recurring themes in discussions on the management of research in Britain since the Barber Report on scientific staff and earlier, and the second and third recommendations of the present report reiterate the vital importance of effective management. However, no guidance is offered concerning the selection of technical and administrative talent or on how best such a central core should be given the necessary authority. The emphasis placed on the responsibility of industry, Government and the universities in training and developing more managers and project engineers, who combine thorough understanding of the technology they manage with mastery of the art of leadership, finds some reflexion in the report, and recognition of that responsibility lies to some extent behind the present move towards the establishment of business schools. Beyond this, the report recommends that companies should actively seek to assist their most talented man-power to increase and replenish its professional competence. Furthermore, it advocates more systematic study of the art and science of research management, with support from both industry and Government. Intensive study of the experience of modern corporations that are heavily committed to research and innovation is particularly recommended; this finds support in the evidence which Sir Ronald Holroyd gave to the Sub-Committee of the Estimates Committee, which recently reported on the Treasury Control of Establishments. Finally, the Committee considers that wastage of scientific and engineering talent would best be minimized by improved management on the lines suggested and that no fundamental overhauling of Government procurement methods or imposition of extreme controls over contractors is required. However, it believes that co-ordinated action by industry and Government could stimulate more research and development in areas of the economy where the rate of innovation has been relatively slow.

Precisely how this 'action' could be stimulated is not indicated in the report and it would not appear that the United States has yet any real solution to offer to one of the most acute problems besetting the research associations in Britain, or the utilization of science in backward industries generally. The seven recommendations relating to the universities and other institutions of higher education are likewise of particular interest in the light of the recommendations of the Robbins Committee and emphasize many of the same principles—though without offering much further guidance. While the Committee stresses the responsibility of the universities in maintaining a proper balance between teaching, research and public service—with the systematic co-operation of the Federal Government—and admits that better ways are needed to recognize and reward the distinguished teacher, it can only remind the universities and professional associations that they have given too little attention to this subject. It suggests they might, with the President's

Science Advisory Committee, indicate some more effective means of recognizing great teachers and creative contributions to teaching.

One of the recommendations calls for development of new centres of educational excellence in science as well as further support of the efforts of the present centres and, as is now being done in Britain, increased attention to and larger support of programmes for the development and reform of curricula, particularly programmes which involve outstanding scholars in the universities working with school teachers. It is also in line with the Robbins Report that universities with strength in science should accept a responsibility to provide opportunities for study and research for members of the faculty of independent liberal arts colleges, and that such colleges should strengthen the quality of their science teaching by increased salaries, research facilities and leave for professional development. In view of the present discussion on engineering education in Britain, it should also be noted that the Killian Committee recommends strengthening and expanding graduate study in engineering as well as continued reform of undergraduate education in engineering, reducing its rigidity and increasing its scientific content, and modernization of the laboratory facilities of engineering schools.

The final two recommendations also reflect present-day tendencies in Britain. Universities, it is urged, in close co-operation with Government and industry, should develop a concerted attack on the problem of keeping engineering and scientific man-power up to date by refresher and like courses. Universities should also take the lead in expanding educational research, and the Committee rightly argues that reform of curricula, improvements in engineering schools, expansion of teacher training, and the establishment of new centres of excellence all require a sound foundation in research.

This aspect is further discussed in a separate chapter, "The Need for Research", in which the Committee recommends that the Government, industry and the universities expand or initiate research efforts that will provide the broader perspectives and increased knowledge for dealing more effectively with the issues involved in the utilization of scientific and engineering man-power. As examples, it instances the economics and dynamics of scientific and engineering man-power, the unused potential in human resources, technological aids, the organization in its operating environment, the scientist or engineer in his working environment, and scientific and engineering man-power and public policy. Some of these subjects are already being investigated in Britain under programmes for educational research financed by the Ministry for Education and Science. Others fall within the scope of the Committee on Scientific Man-power of the Advisory Council for Scientific Policy, and there should be no reason to fear that such efforts will be interrupted by the changes which are being made in the organization of Civil science following the recommendation of the Trend Report (*Nature*, 203, 574; 1964).

The significance for Britain of this report from Dr. Killian and his colleagues does not, in fact, lie so much in the novelty of its recommendations as in the clarity and firmness with which they are related to national needs, whether in the United States or in Britain. No Government can now mistake the massive influence which it exerts on the deployment and utilization of scientists and engineers or the concomitant extent of its responsibility to avoid waste. The balanced allocation of such talent, based on adequate and reliable data, is primarily a Government responsibility and, if management also has a key part to play, that in itself indicates the Government's duty to satisfy itself that adequate means for education and training in management are available. Above all, there must be forethought and adaptability to change, and in this report standards are set and challenges offered which must be accepted at least as much in Britain as in the United States.

A LOOK AT LIFE

Atlas of Electron Microscopy

Biological Applications. Compiled by F. Scanga. Pp. xxvi + 331. (Amsterdam, London, New York: Elsevier Publishing Company, 1964.) 210*s*.

THE electron microscope is now firmly established as a tool inseparably bound to future progress in biology, and no biological laboratory can in the future be considered complete without this now essential tool. Most biology students at universities, indeed, already have direct if somewhat glancing acquaintance with the instrument and none can have escaped its influence. So much indeed has electron microscopy become part of the corpus of common biological tools, and so fundamental has been its impact on biological thought, that most sixth formers already know a good deal about the instrument and its achievements, and electron microscopy at a suitable level is about to take its place in the formal curriculum at schools. This is perhaps the first time in which current biological research, however exciting, has found an immediate outlet both in text-books and in school curricula. Whatever satisfaction one may find in this rapid spread of modern knowledge is tempered by a concern that, if the principle is to be maintained that no student should be taught matters which he cannot be called on himself to experience, however remotely, something must be done to bring practical electron microscopy within the ambit of all universities and of all schools dealing with advanced level biology. This has been foreshadowed by recommendations made in several quarters that schools should arm themselves with a sheaf of relevant, informative electron micrographs produced by recognized authorities. Steps are already being taken to publish sets of electron micrographs collected together specifically for this purpose. But steps take time, and time may be something the schools are short of. It was therefore with the keenest anticipation that I received this beautifully presented volume by Prof. Scanga. It constitutes a second edition, in English, of an earlier volume in Italian by the same author. The first edition was chiefly devoted to bacteriology and virology, but this second version "has been supplemented by a large number of micrographs of cytological interest. In all, about 25 per cent of the photographic material is new to the present edition".

The book consists of 482 electron micrographs each briefly annotated together with a "brief but useful survey" of the fundamental techniques and principal biological applications running over little more than eleven pages of text. Some of the micrographs are of historic importance and some are excellent—chance alone would ensure this—but it is disheartening on looking through these pages to see so many which, "notable achievements of workers throughout the world" though they may be, are neither historically important, excellent, recent nor produced by a recognized authority. Most of the micrographs dealing with bacteriology and virology, and some other micrographs are Prof. Scanga's own and it is understandable and welcome that an author should draw on his own richness. 148 micrographs of bacteria in a total of 482 illustrations seems, however, to be going a little far particularly since many of them show exactly the same (few) features. The book would have been greatly improved if most of these had been deleted or, preferably, replaced by more recent plates on most of the topics which are covered in this book and many which are not. Scarcely any of Prof. Scanga's photographs, moreover, come from a named published work so that the viewer has no possibility of following up any point of interest. Of the fewer than 240 items which refer to published papers, only two are more recent than 1960 and more than half were published during the 10 years preceding 1956. One can scarcely believe, therefore, that "the present day scope and utility of electron microscopy" has been adequately documented. One of the potentially good features of the book, the large format "chosen so that the original electron micrographs may be seen to their best advantage", has unfortunately in many cases, though happily not all, gone sadly astray: it has resulted in magnification which many of these earlier photographs could not stand.

This having been said, there are still many photographs in this book which are excellent and well worth recording in this way. It would be invidious to name names, and interested biologists are recommended to leaf through the book to look for these highlights. The total effect, nevertheless, leaves a doubt in my mind about the public for which this book has been prepared. It can scarcely appeal to the expert and, taking into account the amount of information conveyed, can scarcely appeal to schools at this price even though at the same time the price seems moderate for a magnificently produced volume of this kind. Electron microscopy is at this time advancing more rapidly than almost any other facet of scientific endeavour and a collection of photographs is inevitably out of date to-day even if culled from yesterday's efforts. It is sad that this book appears to have been out of date even before it was conceived, for the idea was sound and Prof. Scanga appears to have missed a unique opportunity.

R. D. PRESTON

COPEPODA AND BRANCHIURA

Parasitic Copepoda and Branchiura of Fishes

By Satyu Yamaguti. Pp. vii + 1104 (333 plates). (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1963.) 563*s*.

THE number of known species of Copepoda and Branchiura, mainly parasitic on fishes, has now passed 2,500 and keeps rising from month to month. It includes a diversity of forms which is as bewildering as it is fascinating. Many of these forms have become enmeshed in the tangle of systematic controversy, many have never been properly studied or even sufficiently described. A synoptic look at the entire group has been long overdue.

This book is an attempt to produce a comprehensive account of the copepods and branchiurans infesting fishes. Its author is a noted helminthologist, well known for his magnum opus, *Systema Helminthum*. By his own admission (p. 1), he treats Copepoda as a second string to his bow. Closer acquaintance with his book bears him out entirely.

I began my appraisal of Yamaguti's book by a close investigation of its bibliography. Although the author himself does not consider it complete, the bibliography is surprising by its lack of selectivity. Some important publications are missing. On the other hand, some of the included ones are irrelevant to the subject discussed. Papers by Blake and Bonnier (p. 346) do not deal with the parasites of fishes. The list could have been better edited. Some references are quoted twice under different dates (Brian, 1898, 1908) or under different authors (Nunes-Ruivo, 1952; Pearse, 1952). There is even one reference to a paper never published (p. 362, Kirtisinghe, 1934, in *Spolia Zeylanica*). These, and many more, create an aura of untidiness which does little to inspire confidence. The aura is further augmented by fairly numerous typographical errors. One is rather taken aback at seeing a proposal to amend *Lernaeopodina* to . . . *Lernaeopodina*, particularly when there is really no need for amendment. *Phrixocephalus arboreus* is quoted in the index twice, the second time as *alboreus*. (On the other hand, *Lernaeocera* is missing from the index altogether.)

The book is intended as a complete record of all known species but it falls short of its aim. Many species have been missed out. Even some genera are absent. *Anaclavella* and *Euclavellisa* are not mentioned, though the paper in which they were first described (Heegaard, 1940) is recorded in the bibliography.

A disagreeable feature of the book is its taxonomic confusion with its inevitable consequences. Many species are recorded twice under different names (for example, *Cybicola armatus*, p. 135, and *Pseudocycnoides armatus*, p. 172; *Chondracanthus horridus*, p. 273, and *Disphaerocephalus horridus*, p. 286; *Clavella hippoglossi*, p. 243, and *Hatschekia hippoglossi*, p. 135). The last example is particularly glaring: *C. hippoglossi* was validly transferred to the genus *Hatschekia* in 1902. Similarly, the confusion between *Lernaeocera* and *Lernaea* was resolved in 1915, but it still haunts Yamaguti's pages. The confusion is further increased by the author's revival of long-defunct names. *Salmincola*, a well-established generic name, is replaced by Lamarck's *Entomoda*, on the ground that *Entomoda* (later *Salmincola*) *salmonea* was mentioned first in the account of the genus. Contrary to Yagamuti's view, the International Committee for Zoological Nomenclature decided some time ago that in Lamarck's genera no species will be accepted as type by implication. Equally unfounded, in my opinion, is the substitution of *Chondracanthoides* Oakley, 1930, for *Chondracanthodes* Wilson, 1932.

One of the penalties of nomenclatural inaccuracies is the placing on record of non-existing species such as *Dissonus intermedius* Kurtz, 1932. Kurtz published no paper in that year. She did, however, describe *Pholidopus* (*Achtheinus*) *intermedius* in 1924, establishing in the same paper *Dissonus glaber*. Yamaguti lists also, on p. 114, *Achtheinus intermedius* as synonymous with *Dissonus intermedius*. The two genera are not even in the same family.

It is not surprising, in view of the foregoing, that one tends to approach the author's systematics with caution. Some of it, such as the erection of the new order Andreinidea (consisting of only one species), seems to me to be of questionable value. The chondracanthids are a diverse lot, biologically as well as morphologically, and the isolation of *Andreina* in a separate order seems scarcely justifiable. Why not, for example, *Juanettia*, with its peculiar mandible? In contrast to this innovation is the retention of Chondracanthidae and Lernaeopodidae in the same order, though it is now known that the two families are not related.

The phylogeny of the parasitic copepods is still very controversial and one cannot expect to find agreement with everybody. One must not, however, confuse the sides in the dispute. This is what the author does by mentioning in the same breath, as it were, Lang and Heegaard, on p. 2.

At the level of the lower taxa, thirteen new families are introduced; it would be a bold man who would give a snap judgement on their validity. The author disregards, however, Gurney's (1933) Lernaeoceridae. He decides to retain Lernaeocerinae and Lernaeinae in the same family, in spite of strong evidence, produced during the past two decades, that close affinity exists between *Lernaea* and *Lamproglena* (placed by Yamaguti in Eudactylinidae), and in spite of many indications that a careful revision in that sector might not come amiss. At the generic level, the author retains Leigh-Sharpe's spurious genus *Alella*.

His new combination of *Isobranchia* is an interesting effort to clarify the uncertain status of the *Brachiella* group, but it does require further investigation. Yamaguti's support for Leigh-Sharpe's 'splitting' of *Clavella*, abundantly rejected many years ago, is not acceptable to me.

On the credit side of the book is most of all its existence. The task it set out to fulfil is an onerous one and its author is to be admired for his courage and diligence. The gathering together, in 333 plates, of illustrations, usually dispersed to the point of inaccessibility, is in itself a feat and a tremendous help for anybody working in this field. In spite of its many and obvious shortcomings, in spite of its uncomfortably high price, the book will become essential. Those who use it, however, and beginners in particular, would do well to double-check every piece of information it provides.

Z. KABATA

IMMUNOLOGICAL REVIEWS

Progress in Allergy

Vol. 7. Edited by Paul Kallós and Byron H. Waksman. Pp. xii+334. (Basle and New York: S. Karger, 1963.) 60 Sw. francs.

THE seventh volume of *Progress in Allergy* fully maintains the high standard of its predecessors. This series of volumes consists of reviews of immunology that are usually comprehensive and therefore provide one of the standard sources of reference to the immunological literature. This volume is no exception and contains five important review articles.

In the first article, H. Fudenberg presents a concise review of the "Hereditary Gamma Globulin (Gm) Groups". This field involves the investigation of genetically determined differences in the antigenic properties of human γ-globulin, which can be revealed only by the use of naturally occurring antibodies in certain human sera. It is well known that sera from the majority of patients with active rheumatoid disease contain antibodies to human γ-globulin; it now appears that these naturally occurring antibodies can detect antigenic differences between the γ-globulins of different human individuals. Fudenberg points out that the antigens (allotypes) are readily identified by agglutination-inhibition reactions in a way analogous to the use of inhibition-reactions in investigating the genetically determined antigens of human erythrocytes. He describes the incidence of the allelic γ-globulin determinants (Gm phenotypes) in various ethnological groups; then follows a description of the physicochemical and serological properties of the components of the Gm test system itself.

The author describes his own attempts to simplify the cumbersome test system and discusses the implications of recent work relating Gm specificities to the structure of γ-globulin. It is evident from his review that there is already a need for standardization of nomenclature and test systems in this new field.

Anaphylactic shock has long been considered to involve a reaction of the body to pharmacologically active substances, released from cells or tissues, by the interaction of antigens and antibodies in the immediate vicinity of body tissues. However, little is known of the mechanisms underlying these tissue reactions, and increasing attention is now being directed to the biological effects of preformed antigen-antibody complexes. K. Ishizaka is a leading worker in this field; the second chapter of this volume consists of his review entitled "Gamma Globulin and Molecular Mechanisms in Hypersensitivity Reactions".

In the first part of his article, Ishizaka brings together the biological activity of immune complexes and their immunochemical properties. Complexes formed in moderate antigen excess have the greatest biological activity; they produce acute anaphylaxis in the guinea pig or mouse, and cause contraction of smooth muscle as well as passive cutaneous anaphylaxis. The author discusses the discrepancy between the vascular lesions seen in serum sickness, or in the Arthus phenomenon, and the lesions that result from the injection of preformed immune complexes; he suggests that greater fixation (and hence greater damage) to blood vessels occurs when the immune complexes are actually formed *in vivo*. Both skin reactivity and complement-fixing potency depend on the species of origin of the antibody as well as the ratio of antibody to antigen; it appears that two or more antibody molecules attached to one antigen are required for skin reactivity.

Ishizaka then suggests that important structural changes in antibody molecules may occur when they are brought together by antigen and that certain molecular shapes arise (toxic configurations of the γ-globulin) that acquire the capacity to liberate pharmacologically active substances from skin and other tissues. Ishazaka's findings relate to present thinking on the co-operative properties of large molecules that go beyond the properties of their sub-units; the author's experimental work is discussed in some detail and there is a valuable bibliography.

"Organ specificity with special reference to the lens" is the title of a well-documented review by S. P. Halbert and W. Manski. They examine the concepts of organ-specific and species-specific antigens using their extensive data on ocular lens antigens as a starting point. Further illustrations are drawn from some of the literature on: serum proteins and blood cells; heart and skeletal muscles; spermatozoa and brain; cell nuclei, DNA, enzymes and hormones. It is proposed that organ specificity and species specificity represent extremes of a spectrum of differentiation and that the vertebrate lens provides a classical example of the organ-specific antigens. Antisera to bovine and human lens were made in rabbits and ducks; there were many precipitin cross-reactions with higher vertebrate lenses, but only a few with the lower vertebrate lens extracts, while invertebrate lens did not react at all.

Serum proteins were once thought to reflect the individuality of their species of origin; however, as Halbert and Manski point out, considerable antigenic sharing is now evident in serum proteins from a wide range of species. It is implied that organ- and species-specificity are not mutually exclusive properties of tissue antigens; though few will disagree with this, there will be some differences of opinion concerning the nomenclature used in this review.

The literature on auto-antibodies to lens is reviewed together with selected examples of other tissue auto-antibodies and a critical discussion is given of the status of auto-allergic lens disease. The authors' opinion is that further work will be needed before it is clear that auto-antibodies can damage the lens *in vivo*, or cause damage to cultured lens epithelium *in vitro*.

It is concluded that advances in techniques of immunodiffusion will now permit a greater degree of accuracy in the application of tissue immunochemistry to problems of differentiation and taxonomy.

In a chapter entitled "Induced Synthesis of Histamine, Microcirculatory Regulation and the Mechanism of Action of the Adrenal Glucocortoid Hormones", R. W. Schayer cites evidence implicating histamine in the physiological regulation of the microcirculatory system. It is explained that this view "is in sharp contrast to the usual concept of histamine as a nuisance or toxin". In a closely packed presentation the author enumerates the evidence that regulation of the microcirculation occurs *via* the production of newly synthesized histamine molecules. This is made possible by an increase in histidine decarboxylase activity that occurs after various stimuli; this enzyme activity is shown to depend on the severity of the stimulus and to correlate with the degree of capillary response.* The author closely evaluates other permeability factors (plasma globulins, leucotaxines and plasma kinins) and considers that they are not involved in microcirculatory regulation.

Schayer then discusses the modes of action of glucocorticoids as vasoconstrictors of the smooth muscle of the microcirculation and possible potentiators of catecholamines; thus these two actions of the glucocorticoids would combine to inhibit the effects of induced histamine on the microcirculation. The author tabulates the response of the microcirculation to various circumstances, interpreting the observed changes in terms of a balance between induced histamine synthesis on one hand and glucocorticoid status on the other.

Finally, S. B. Salvin contributes an article entitled "Immunological Aspects of the Mycoses". He reviews the fungal antigens, antibodies and serological tests in eleven mycotic diseases, while he further discusses delayed hypersensitivity, pathogenesis, resistance and immunization in these disorders. The mycoses reviewed are as follows: Actinomycosis, nocardiosis, aspergillosis, candidiasis, cryptococcosis, North American blastomycosis, coccidioidomycosis, histoplasmosis, chromoblastomycosis, sporotrichosis, and dermatomycosis. This is a monumental review, containing nearly 800 references to the literature, though clinical mycologists may notice the absence of data concerning *Mucor*, *Rhizopus*, and *Absidia*. The alarming increase in deep-seated mycotic disease that has occurred during the past ten years makes Salvin's review most timely: its value is thus two-fold, for there is a growing increase in the immunology of Fungi in general.

As can be seen from the contents, this volume richly deserves its place in the reference literature of Immunology. In an introduction, Waksman summarizes recent developments in immunology and makes a plea for the recognition of Immunopathology as a special discipline, and for the introduction of a journal devoted to this speciality. Those who eagerly await the appearance of each, now annual, addition to the *Progress in Allergy* series will agree that these reviews make a great contribution in themselves.

D. C. DUMONDE

ANALYSIS OF PLANT DISEASE EPIDEMICS

Plant Diseases

Epidemics and Control. By J. E. van der Plank. Pp. xvi+349. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963.) 80*s*.

THOSE who know Dr. van der Plank or are aware of his substantial contributions to the epidemiology of plant diseases will not be led astray by the title of this book, but others may be. It is not, as one might anticipate, a description of plant disease epidemics and how to control them, but a dissertation on new methods of epidemiological analysis based on the rate at which the population of the pathogen increases (infection rate) and on the relation between the amount of inoculum and the amount of disease the inoculum produces. It also demonstrates how this kind of analysis can be applied in the control of diseases, whether by the use of resistant varieties, by sanitation or by chemicals, all of which help to reduce the amount of inoculum, or the infection rate, or both.

Plant Diseases: Epidemics and Control is intended primarily for plant pathologists and for plant breeders interested in breeding for resistance to diseases, and some of it is likely to be heavy going for those without an adequate knowledge of mathematics or who lack interest or experience in the application of mathematics to biology. The author, convinced that training in epidemiology will soon become as essential for a plant pathologist as training in mycology, virology or genetics, is clearly aware of this difficulty for he goes out of his way to help his readers. The first of the twenty-three chapters explains simply and clearly what the book is about and there is a continuous explanatory thread, in part taking the form of an introduction to each chapter, which runs through the text, encouraging and maintaining interest even through the more difficult parts. Exercises in epidemiological analysis are included at the end of each of the chapters concerned with methods, and relevant mathematical tables are provided in an appendix. The other early chapters deal with analogies drawn between rates of interest on money and disease infection rates; with methods for plotting the progress of an epidemic; and with the breakdown and analysis of infection rates to reveal how they may be influenced by various factors, such as the time newly infected tissues take to become infectious (latent period) and the time needed for symptoms to develop (incubation period), or by the effects of new host growth, gradual sterility of infected tissues and so on.

The rest of the book is mainly devoted to the illustration of how the practice of sanitation or the use of resistant varieties and fungicides may be related to the analysis of control. The effect of sanitation, very loosely defined as the process of reducing the inoculum from which an epidemic starts, is dealt with in three chapters, with special reference to potato blight, black stem rust of wheat, bunt of wheat and *Fusarium* wilt of tomato. Then follow seven chapters on types of disease resistance, again with potato blight and black stem rust as the cardinal examples. A clear distinction is made between vertical resistance, which is directed against some races of a pathogen but not others, and horizontal resistance (in potatoes at present called field resistance) which operates against all races. The need for and intent of this new jargon is less apparent. Vertical resistance, the usual choice of plant breeders, is preferred by the author only when there is a record of variety stability or when the disease multiplies slowly. Horizontal resistance is preferred when varietal change is frequently imposed by rapid changes in the races of the pathogen or when it is desired to improve the performance of fungicides. In biological warfare with black stem rust, for example, vertical resistance would, it is thought, leave the wheat crop wide open to destruction, whereas horizontal resistance is believed to provide an adequate defence. In chemical control of diseases, regarded here at times as a form of sanitation, the fungicidal action of the chemical is only part of the story. Successful control of an epidemic depends almost equally on weather or other environmental conditions and could be greatly promoted by better horizontal resistance in the host plants.

The text ends with two chapters on the spread, as distinct from the increase, of disease. In the second of these, the author is highly critical of many field experiments intended to provide information that can be applied to farming. In his view, experimental plots frequently do not represent accurately the farmer's fields or orchards they are meant to, because of 'representational' and 'cryptic' errors. Such errors arise, for example, when guard rows in conventional layouts are not efficient against fast-moving pathogens in reducing or preventing plot interference, and the extent of the errors may depend on other factors, including plot size and shape. Special layouts for avoiding interference and reducing representational errors are suggested. More than 200 literature references are listed, most of them to work published in the past decade.

This extremely well-written book can be of absorbing interest, even to one who finds much of the mathematics beyond him. It breaks new ground with new ideas and will without doubt lead to much discussion and argument among plant pathologists and plant breeders as well as in a wider field, for much of it will surely find a place in future training courses.

W. C. MOORE

A COMPREHENSIVE GUIDE TO TEMPERATURE

Temperature: Its Measurement and Control in Science and Industry

Vol. 3. Editor-in-Chief: Charles M. Herzfeld. Part 1: Basic Concepts, Standards and Methods. Edited by F. G. Brickwedde. Pp. xvi + 848. 220*s.* net. Part 2: Applied Methods and Instruments. Edited by A. I. Dahl. Pp. xiv + 1094. 236*s.* net. Part 3: Biology and Medicine. Edited by James D. Hardy. Pp. xii + 683. 180*s.* net. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1962–63.)

THE American Institute of Physics, associated with the National Bureau of Standards and other organizations, has sponsored a series of symposia on temperature measurement. So far there have been four symposia, in 1919, 1939, 1954 and 1961, and the proceedings of the last three have been published as volumes 1–3 of *Temperature: Its Measurement and Control in Science and Industry*. The first volume, of 1362 pages, was so comprehensive and authoritative that it immediately established itself as essential in any laboratory concerned with the measurement of temperature. The second volume did not, perhaps, fully justify the title. It ran to 467 pages, and industrial applications were only very lightly touched on.

The third volume has now appeared and is so large that it has had to be published in three parts, totalling 2625 pages, and one can say at once that it is going to be fully the equal of the famous Volume 1 as an essential reference work. Volume 1, however, has lost none of its usefulness, for little of its contents has become obsolete, but the new volume introduces much new matter. It is clear that many of the recent developments arise from space research, which has posed many problems, notably in the measurement of gas and flame temperatures and in the physiological questions involved in space travel.

The new volume contains 242 papers, ranging from accounts of particular instruments or investigations to general survey papers. In the field of optical pyrometry, for example, we have papers by R. D. Lee of the National Bureau of Standards in Washington and by J. Middlehurst and T. P. Jones of the National Standards Laboratory of Australia, each describing the photoelectric instruments developed in those laboratories, while from Canada D. R. Lovejoy contributes a notable survey paper under the title "Recent Advances in Optical Pyrometry". In this we have an account of work carried out by the author, who also considers the work of many other investigators. References to fifty-three related papers are given. The large number of references is a feature of the book as a whole: there are, on the average, about twenty-five to each paper, and they add greatly to the value of the book as a work of reference.

Part 1, *Basic Concepts, Standards and Methods*, is notable for the contributions from national laboratories in the United States, the United Kingdom, the Soviet Union, Germany, the Netherlands, Canada and Australia, dealing with the relationship between the thermodynamic and practical scales of temperature. One of the main problems in this field at the present time is the method to be used for extending the International Practical Scale of Temperature below 90° K (the boiling point of oxygen) and a group of five papers is devoted to it. Another group of eight papers deals with the establishment of the thermodynamic scale by both traditional and novel methods. "A Review of Recent Determinations of Thermodynamic Temperatures of Fixed Points above 419° C" is another important survey paper. It is contributed by Dr. H. Moser, of the Physikalisch-Technische Bundesanstalt, and summarizes the results obtained by gas thermometry in Germany, Japan, the United States and the U.S.S.R., and discusses possible sources of error.

Notable among a group of papers on platinum resistance thermometry is "Potentiometric Methods of Resistance Measurement", by T. M. Dauphinee, of the National Research Council, Ottawa. Like Lovejoy's optical pyrometer paper from the same laboratory, it is a valuable survey and incorporates some of the author's recent work, notably the design of a resistance comparator utilizing a circuit in which the terms of the quadratic law of a platinum thermometer can be set so that the bridge reads directly in temperature with an accuracy of 0·001° C from − 50° to 700° C with a thermometer having a fundamental interval of approximately 10 ohms.

Part 1 also includes several papers on the measurement of plasma temperatures by spectroscopic and other methods, on temperature measurement in astrophysics and in geophysics.

Nearly all the papers on thermoelectric methods are to be found in Part 2, Applied Methods and Instruments. The contribution "Thermocouple Materials", by F. R. Caldwell, of the National Bureau of Standards, is very comprehensive, and includes most of the physical properties of the metals and alloys which are ever used in thermocouples. This paper gives 124 references. In all, there are 24 papers in the sections on thermoelectric thermometry, dealing with such matters as couples for very high temperatures, e.m.f. stability and performance when exposed to nuclear reaction. There are, however, further papers in other sections on the use of thermocouples for special purposes, such as the measurement of surface temperatures, gas temperatures, transient temperatures, etc. There is also a paper by S. D. Raezer and H. L. Olsen on "The Intermittent Thermometer: A New Technique for the Measurement of Extreme Temperature", which discusses the application of a chromel-alumel thermocouple to the measurement of temperatures well above its melting point by a method of intermittent exposure. Temperature measurements of a plasma jet up to nearly 4,000° K by this method are reported, and the work is being continued in the hope of further extending the range of the method.

Clarence R. Droms reports on an extensive series of tests on the stability of thermistors, while other papers concerned with semi-conductor devices range from the use of thermistors and carbon resistance thermometers at low temperatures to the possible use of ceramic elements for temperatures above 2,300° R (1,000° C).

Radiation thermometry is also well covered in Part 2. There are four papers devoted to both monochromatic and radiation ratio pyrometers, and to their uses in the measurement of gas and plasma temperatures.

Part 3 is concerned with biology and medicine, but many of the experimental techniques will find use in more extended fields. There are, for example, papers on microcalorimetry by T. H. Benzinger and Charlotte Kitzinger and by Robert L. Berger, and a study of the conditions required for accurate surface temperature measurement with thermocouples by George W. Molnar and Joseph C. Rosenbaum, jun. The paper by T. H. Benzinger and G. W. Taylor on "Cranial Measurements of Internal Temperature in Man" gives an ingenious brush design for a thermocouple to maintain light contact on the eardrum which could find other uses. The importance of the measurement of cranial temperatures is clear from the paper on "The Human Thermostat", by T. H. Benzinger, C. Kitzinger and A. W. Pratt. This paper is a very thorough investigation of the mechanism of temperature control in the human body. Other sections of Part 3 are devoted to thermal sensation, hypothermia and the physiological responses to heat and cold.

The three parts of Volume III of *Temperature: Its Measurement and Control in Science and Industry* should all find a place in any laboratory in which the problems of measuring temperature are encountered. The sponsors, publishers, editors and contributors are to be congratulated on a valuable piece of work. J. A. HALL

THE MYSTERY OF THE COSMIC HELIUM ABUNDANCE

By PROF. F. HOYLE, F.R.S., and DR. R. J. TAYLER
University of Cambridge

IT is usually supposed that the original material of the Galaxy was pristine material. Even solar material is usually regarded as 'uncooked', apart from the small concentrations of heavy elements amounting to about 2 per cent by mass which are believed on good grounds to have been produced by nuclear reactions in stars. However, the presence of helium, in a ratio by mass to hydrogen of about 1 : 2, shows that this is not strictly the case. Granted this, it is still often assumed in astrophysics that the 'cooking' has been of a mild degree, involving temperatures of less than 10^8 K, such as occurs inside main-sequence stars. However, if present observations of a uniformly high helium content in our Galaxy and its neighbours are correct, it is difficult to suppose that all the helium has been produced in ordinary stars.

It is the purpose of this article to suggest that mild 'cooking' is not enough and that most, if not all, of the material of our everyday world, of the Sun, of the stars in our Galaxy and probably of the whole local group of galaxies, if not the whole Universe, has been 'cooked' to a temperature in excess of 10^{10} K. The conclusion is reached that: (i) the Universe had a singular origin or is oscillatory, or (ii) the occurrence of massive objects has been more frequent than has hitherto been supposed.

The values of the helium to hydrogen number ratio determined for various objects are shown in Table 1.

Table 1

	He/H
Orion nebula (ref. 1)	0·091
NGC 604 in *M* 33 (ref. 2)	0·102
Small magellanic cloud (ref. 3)	0·11
B stars (ref. 4)	0·16
Planetary nebulæ (ref. 5)	0·09–0·19
Solar cosmic rays (refs. 6 and 7)	0·091
Solar evolution (ref. 8)	0·09

The first five determinations were made by spectroscopic methods. It has been found that the ratios of carbon, oxygen, magnesium and silicon in solar cosmic rays are in good agreement with well-determined spectroscopic values, and it is therefore argued that the composition of the cosmic rays reflects the true solar composition, and hence that the He/O value in the cosmic rays reflects the true solar helium/oxygen ratio. Given reliable spectroscopic values for all elements other than helium, and given accurate opacities within the Sun, it is possible to determine He/H from the requirement that solar evolution must be such that the present-day luminosity is arrived at after $4{\cdot}5$–5×10^9 years, the known age of the solar system. It is of immediate interest that two such different methods as these should arrive at closely the same result for the solar He/H value, particularly as this result—if accepted—is sufficient to establish that the Universe did not have a singular origin, nor can the Universe be oscillatory.

A high helium abundance in some particular star or nebula need not be taken as proof of a high primeval value, since helium may have been produced locally by nuclear reactions. For this reason low values of He/H are of more interest in relation to the original composition of the Galaxy than high values. However, O'Dell's high value of $0{\cdot}18 \pm 0{\cdot}03$ for the planetary nebula *M* 15 is of special interest because O'Dell also finds a low value for the ratio O/H, suggesting that the material of this nebula may not have been adulterated by the products of nuclear reactions. Adulteration by hydrogen-burning could have occurred; but not adulteration by helium-burning, so the situation remains rather uncertain.

We begin our argument by noticing that helium production in ordinary stars is inadequate to explain the values in Table 1, if they are general throughout the Galaxy, by a factor of about 10. Multiplying the present-day optical emission of the Galaxy, $\sim 4 \times 10^{43}$ ergs sec^{-1}, by the age of the Galaxy, $\sim 3 \times 10^{17}$ sec, and then dividing by the energy production per gram, $\sim 6 \times 10^{18}$ ergs g^{-1}, for the process H → He, gives $\sim 2 \times 10^{42}$ g ($10^9 M_\odot$). This is the mass of hydrogen that must be converted to helium in order to supply the present-day optical output of the Galaxy for the whole of its lifetime. Allowance for emission in the ultra-violet and in the infra-red increases the required hydrogen-burning, but probably not by a factor more than ~ 3. Since the total mass of the Galaxy is $\sim 10^{11} M_\odot$ the value of the He/H to be expected from H → He inside stars is only $\sim 0{\cdot}01$. While it is true that the Galaxy may have been much more luminous in the past than it is now, there is no evidence that this was the case.

Next, we shift the discussion to a 'radiation origin' of the Universe, in which the rest mass energy density is less than the energy density of radiation. The relation between the temperature T_{10}, measured in units of 10^{10} K, and the time t in seconds can be worked out from the equations of relativistic cosmology and is:

$$T_{10} = 1{\cdot}52\, t^{-1/2} \qquad (1)$$

In the theory of Alpher, Bethe and Gamow[9] the density was given by:

$$\rho \approx 10^{-4} T_{10}^{3} \text{ g cm}^{-3} \qquad (2)$$

a relation obtained from the following considerations. The material is taken at $t = 0$ to be entirely neutrons. At $t \simeq 10^3$ sec, $T_{10} \simeq 0{\cdot}05$, approximately half the neutrons have decayed. If the density is too low the resulting protons do not combine with the remaining neutrons, and very little helium is formed. On the other hand, if the density is too high there is a complete combination of neutrons and protons, and with the further combination of the resulting deuterium into helium very little hydrogen remains as t increases. Thus only by a rather precise adjustment of the density, that is, by (2), can the situation be arranged so that hydrogen and helium emerge in approximately equal amounts.

It was pointed out by Hayashi[10] and Alpher, Follin and Herman[11] that the assumption of material initially composed wholly of neutrons is not correct. The radiation field generates electron-positron pairs by:

$$\gamma + \gamma \rightleftarrows e^- + e^+ \qquad (3)$$

and the pairs promote the following reactions:

$$n + e^+ \rightleftarrows p + \bar{\nu} \qquad (4)$$

$$p + e^- \rightleftarrows n + \nu \qquad (5)$$

The situation evidently depends on the rates of these reactions. It turns out that for sufficiently small t the balance of the reactions is thermodynamic. This means that not only are protons generated by (4) and (5), but also that the energy densities of the pairs and of the neutrinos must be included in the cosmological equations. At $T_{10} \simeq 10^2$, even μ-neutrinos are produced and these too should be included. The effect of these new contributions to the energy density is to modify (1) to:

$$T_{10} \simeq 1{\cdot}04\, t^{-1/2} \qquad (6)$$

The values of σv for (4), (5), read from left to right, are:

$$\pi^2\left(\frac{\hbar}{mc}\right)^3\left(\frac{W \pm W_0}{mc^2}\right)^2\left(\frac{\ln 2}{(\mathrm{f}\tau)_{\mathrm{lab}}}\right) \qquad (7)$$

in which the well-known Coulomb factor has been taken as unity, and where the symbols have the following significance: m, electronic mass; W, the energy, including rest mass, of the positron or electron; W_0, energy difference between the neutron and proton ($2{\cdot}54\ mc^2$); ± apply to (4) and (5) respectively; $(\mathrm{f}\tau)_{\mathrm{lab}}$, the f$\tau$-value for free neutron decay (1,175 sec).

To obtain the rates of reactions (4) and (5), read from left to right, multiply (7), using the appropriate sign, by the number of positrons/electrons with energies between W and $W + \mathrm{d}W$ and then integrate the product with respect to W from zero to infinity. The corresponding values for the rates of (4) and (5) read from right to left can then easily be obtained by noticing that in thermodynamic equilibrium:

$$\frac{n}{p} = \exp - \frac{W_0}{kT} \qquad (8)$$

where n, p represent the densities of neutrons and protons.

If, however, one is content with accuracy to within a few per cent it is sufficient simply to write $W = mc^2 + qkT$ in (7) and to multiply by the total number density of pairs. The value then chosen for q is that which makes $mc^2 + qkT$ equal to the average electron energy at temperature T; this is a slowly varying function of T and is given by Chandrasekhar[12]. The pair density is:

$$\frac{1}{\pi^2}\left(\frac{kT}{\hbar c}\right)^3\left(\frac{mc^2}{kT}\right)^2 K_2\left(\frac{mc^2}{kT}\right) \qquad (9)$$

where K_2 is the modified Bessel function of the second kind and second order. For $T_{10} \sim 1$ this expression can be closely approximated by the simple form $30\ a\ T^3/\pi^4 k$. The number density of neutrino-antineutrino pairs (of both kinds) is $15\ a\ T_3/\pi^4 k$.

Adopting this simplified procedure, the reaction rate for $n + e^+ \rightarrow p + \bar{\nu}$ is easily seen to be:

$$0{\cdot}071\ T_{10}^3\ (1 + 0{\cdot}476\ qT_{10})^2 \text{ per neutron per sec} \qquad (10)$$

The effect of $n + \nu \rightarrow p + e^-$ is approximately to double the rate at which neutrons are converted to protons. Using equation (8), the rates of the inverse reactions are obtained by multiplying equation (10) by $\exp - W_0/kT = \exp - 1{\cdot}506/T_{10}$. Hence the following differential equation determines the variation of $n/(n + p)$ with time:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{n}{n+p}\right) = 0{\cdot}142T_{10}^3\ (1 + 0{\cdot}476qT_{10})^2 \times \left[\frac{n}{n+p}\left(1 + \exp\frac{-1{\cdot}506}{T_{10}}\right) - \exp\frac{-1{\cdot}506}{T_{10}}\right] \qquad (11)$$

To express this in a form convenient for numerical integration use T_{10} as the independent variable. With the aid of equation (6):

$$\frac{\mathrm{d}}{\mathrm{d}T_{10}}\left(\frac{n}{n+p}\right) = 0{\cdot}308(1 + 0{\cdot}476qT_{10})^2 \times \left[\frac{n}{n+p}\left(1 + \exp\frac{-1{\cdot}506}{T_{10}}\right) - \exp\frac{-1{\cdot}506}{T_{10}}\right] \qquad (12)$$

Equation (12) can be integrated from a sufficiently high temperature, at which the neutrons and protons are almost in thermodynamic balance, down to the temperature at which the pairs disappear and deuterons are formed. The results are insensitive to starting temperature if it is chosen above $T_{10} = 2{\cdot}5$. When the protons and neutrons are in thermodynamic balance the right-hand side of (12) is zero and the initial value of $n/(n + p)$ is chosen to make this right-hand side zero.

An important question evidently arises as to the precise value of T_{10} down to which equation (12) should be integrated. Rather surprisingly, it appears the deuterium combines into helium, through D(D,n)He^3(n,p)T(p,γ)He^4, at a temperature as high as $T_{10} = 0{\cdot}3$, in spite of the small binding energy of deuterium. (The concentration of deuterium used in establishing this conclusion was just that which exists for statistical equilibrium in $n + p \rightleftarrows \mathrm{D} + \gamma$.) Hence, equation (12) must not be integrated to T_{10} below 0·3. We estimate that integration down to $T_{10} = 0{\cdot}5$ probably gives the most reliable result, because (12) overestimates the rate of conversion of neutrons to protons below $T_{10} = 0{\cdot}5$.

Mr. J. Faulkner has solved the equation for several starting temperatures. Provided $T_{10} > 2{\cdot}5$ initially, he finds $n/(n + p) = 0{\cdot}18$ at $T_{10} = 0{\cdot}5$, giving:

$$\frac{\mathrm{He}}{\mathrm{H}} = \frac{n}{2(p - n)} \simeq 0{\cdot}14 \qquad (13)$$

a result in good agreement with the calculations of Alpher, Follin and Herman[11]. Allowing for the approximation in our integration procedure we estimate that this value is not more uncertain than 0·14 ± 0·02. It should be particularly noted that, unlike the result of Alpher, Bethe and Gamow, this value depends only slightly on the assumed material density; essentially this result is obtained provided the density is high enough for deuterons to be formed in a time short compared to the neutron half-life and low enough for the rest mass energy density of the nucleons to be neglected in comparison with the energy density of the radiation field.

Before comparing this result with observation we note that variations of the cosmological conditions which led to equation (6) all seem as if they would have the effect of increasing He/H. If the rest mass energy density were not less than the sum of the energy densities of radiation, pairs and neutrinos, the Universe would have to expand faster at a given temperature in order to overcome the increased gravity, the time-scale would be shorter and the coefficient on the right-hand side of equation (12) would be reduced. Similarly, if there were more than two kinds of neutrino the expansion would have to be faster in order to overcome the gravitational attraction of the extra neutrinos, and the time-scale would again be shorter; and the smaller the coefficient on the right-hand side of equation (12) the larger the ratio He/H turns out to be.

We can now say that if the Universe originated in a singular way the He/H ratio cannot be less than about 0·14. This value is of the same order of magnitude as the observed ratios although it is somewhat larger than most of them. However, if it can be established empirically that the ratio is appreciably less than this in any astronomical object in which diffusive separation is out of the question, we can assert that the Universe did not have a singular origin. The importance of the value 0·09 for the Sun is clear; should this value be confirmed by further investigations the cosmological implication will be profound. (A similar situation arises in the case of an oscillating universe. The maximum temperature, achieved at moments of maximum density, must be high enough for all nuclei to be disrupted, that is, $T_{10} > 1$. Otherwise, after a few oscillations all hydrogen would be converted into heavier nuclei, and this is manifestly not the case.)

It is reasonable, however, to argue in an opposite way. The fact that observed He/H values never differ from 0·14 by more than a factor 2, combined with the fact that the observed values are of necessity subject to some uncertainty, could be interpreted as evidence that the Universe did have a singular origin (or that it is oscillatory). The difficulty of explaining the observed values in terms of hydrogen-burning in ordinary stars supports this point of view. So far as we are aware, there is only one strong counter to this argument, namely, that there is nothing really special to cosmology in the foregoing discussion. A similar result for the He/H ratio will always be obtained if matter is heated above $T_{10} = 1$, and if the time-scale of the process is similar to that given by equation (6). In this connexion it may well be important that the physical conditions inside massive objects or superstars simulate a radiation Universe. Hoyle, Fowler, Burbidge and Burbidge[13] were led, for reasons independent of those of the present article, to consider temperatures exactly in the region $T_{10} \simeq 1$. These authors give the following differential equation between the time t and the density ρ, in such a superstar:

$$\mathrm{d}t = \left(\frac{1}{24\pi G\rho}\right)^{1/2} \frac{\mathrm{d}\rho}{\rho} \qquad (14)$$

and also the following relation for an object of mass M:

$$\rho = 2{\cdot}8 \times 10^{8} \left(\frac{M_{\odot}}{M}\right)^{1/2} T_{10}^{3}\ \mathrm{g\ cm^{-3}} \qquad (15)$$

Eliminating ρ and $\mathrm{d}\rho$ we have:

$$\mathrm{d}t = \left(\frac{M}{2{\cdot}44 \times 10^{4} M_{\odot}}\right)^{1/4} \frac{\mathrm{d}T_{10}}{T_{10}^{2.5}} \qquad (16)$$

whereas the differential form of equation (6) is:

$$\mathrm{d}t = -\ 2{\cdot}08\ \frac{\mathrm{d}T_{10}}{T_{10}^{3}} \qquad (17)$$

The difference of sign arises because equation (16) was given for a contracting object. For re-expansion of an object the sign must be reversed, so that the time-scales are identical if $M \simeq 5 \times 10^{5}\ M_{\odot}$. It may be significant that this is about the largest mass in which the temperature $T_{10} \simeq 1$ can be reached without the object being required to collapse inside the Schwarzschild critical radius. If collapse inside this radius followed by re-emergence be permitted, larger masses can be considered. The time-scale is then increased above equation (17) and this has the effect of giving a smaller He/H ratio than that calculated above. If an object is inside the Schwarzschild radius and neutrinos do not escape from it, the conditions are closely similar to the cosmological case. On the other hand, the calculation must be slightly changed for objects that do not enter the Schwarzschild radius, since neutrinos are certainly not contained within them. Thus if the same time-scale were used, that is, $M \simeq 10^{5} - 10^{6}\ M_{\odot}$, absence of neutrinos would reduce the right-hand side of equation (12) by a factor of 2. A corresponding calculation leads to $n/(n + p) = 0{\cdot}22$, also in reasonable agreement with observation, especially as all material need not have passed through massive objects. However, a more detailed discussion of massive objects will be required to decide whether the required amount of helium cannot only be produced but also ejected from them.

This brings us back to our opening remarks. There has always been difficulty in explaining the high helium content of cosmic material in terms of ordinary stellar processes. The mean luminosities of galaxies come out appreciably too high on such a hypothesis. The arguments presented here make it clear, we believe, that the helium was produced in a far more dramatic way. Either the Universe has had at least one high-temperature, high-density phase, or massive objects must play (or have played) a larger part in astrophysical evolution than has hitherto been supposed. Clearly the approximate calculations of this present article must be repeated more accurately, but we would stress two general points: (1) the weak interaction cross-sections turn out to be just of the right order of magnitude for interesting effects to occur in the time-scale available; (2) for a wide range of physical conditions (for example, nucleon density) roughly the observed amount of helium is produced.

EXTRACTION OF URANIUM FROM SEA WATER

By R. V. DAVIES, DR. J. KENNEDY, R. W. McILROY and DR. R. SPENCE, C.B., F.R.S.
U.K.A.E.A. Atomic Energy Research Establishment, Harwell
AND
K. M. HILL
U.K.A.E.A. Engineering Group, Risley

THERE is now a world surplus of uranium; the production capacity of mines and ore treatment plants in the United States, Canada and South Africa far exceeds the present demand for all civil and military purposes so that the relatively modest uranium supplies to cover British nuclear power requirements seem to be assured for some years. When the work described here was started, more than ten years ago, this situation was far from evident. It is true that the existence of large reserves in these areas was suspected on geological grounds but there was little reason to expect that production capacity could overtake demand so rapidly. In Britain, we were about to embark on a nuclear power programme which it was thought might lead in course of time to dependence on uranium for much of our national electricity supply, yet no reserves of uranium had been discovered in these Islands which were in any way commensurate with requirements.

The possibility of recovery of uranium from natural waters, including sea water, by ion-exchange resins had been considered by the late Dr. F. H. Burstall and his group at the Chemical Research Laboratory (now the National Chemical Laboratory), Teddington, shortly after the War, but it was decided that the effort should be directed towards exploitation of the then known ores overseas. Later some experiments were made at Harwell[1] on the recovery of uranium from sea water by newly developed techniques of continuous counter-current extraction. The solvent—dibutyl phosphate dissolved in butex (dibutoxy diethyl ether) or kerosene—was contacted with acidified sea water in a rotary annular column; extraction appeared to be quantitative and 60 μg of uranium was obtained from 20 l. It was evident, however, that although such a process would be technically feasible on a large scale the solvent losses and reagent costs would render it economically unattractive. Nevertheless, the comparative ease with which uranium could be quantitatively extracted from such an extremely weak solution containing high concentrations of other salts gave encouragement to the idea that in the long term some economically acceptable method might be found.

The total volume of the oceans has been estimated[2] to be $1{\cdot}37 \times 10^{9}$ cubic kilometres and, assuming a uniform concentration throughout, the dissolved uranium should

amount to $4{\cdot}16 \times 10^9$ metric tons. Moreover, the uranium concentration in sea water is probably stationary; a large amount, estimated at 27,000 tonnes annually, contributed by rivers, appears to be balanced by an equal amount carried down with the bottom deposits[3].

The uranium concentration (3·34 µg/l.) (ref. 4) is remarkably constant; only second-order variations occur between samples obtained from the Atlantic and Pacific oceans and from near the surface to depths of at least 400 m.

The molar concentrations of uranium and of closely associated species in sea water are given in Table 1*a*, and concentrations of other major constituents are given in Table 1*b* (ref. 2).

A very interesting feature is that the uranium occurs in true solution as the tricarbonato complex, $UO_2(CO_3)_3^{-4}$. This was early established at Harwell[5] where it was also shown that less than about 0·1 per cent of the uranium is associated with suspended matter. Russian workers[6] came to the same conclusion regarding the chemical form of the uranium independently. Thus the ocean is virtually a limitless reservoir of uranium in solution in a well-defined chemical environment. There are, however, two major obstacles to using this reservoir as an economic source of uranium. First it is in a strongly complexed form at extreme dilution in presence of relatively high concentrations of other ions; and secondly, to bring any extraction agent into contact with the very large volumes of sea water that would be involved is not an easy operation. To be successful, an extractant must function efficiently at the usual *p*H and ionic strength of sea water and must be virtually insoluble.

Possible Organic and Inorganic Absorbents

An obvious step following the successful solvent extraction experiments with dibutyl phosphate was to incorporate functional groups of similar type in solid insoluble organic resin matrices. Extraction could only be expected by reagents which form a complex with the uranyl ion sufficiently strong to compete with the uranyl tricarbonate complex in sea water for which the stability constant is about 2×10^{18}. Calculation showed that the stability constant of the competing uranyl complex would have to exceed 10^{12}. Although a number of ligands were known to form uranyl complexes with stability constants of this order, such as β-diketones and 8-hydroxyquinolines, the effective stability constant when the ligand had been incorporated in a resin matrix could not be predicted, so a fairly wide range of functional groups was chosen for investigation in the first instance. Resins were prepared[7] containing mono- and di-basic phosphoric and phosphonic acids, 8-hydroxyquinoline, kojic acid, salicylic acid, amino-carboxylic acid and amino-phosphoric acid functional groups. These were tested first in a simulated sea water enriched about 1,000-fold in uranium and afterwards in fresh sea water in a small laboratory on the Mole at Portland Harbour. Samples of chelating resins available at the Chemical Research Laboratory, Teddington, were tested there by Daborn and Milward[8] using the enriched artificial sea water, and the most promising of them, a condensation product of formaldehyde and resorcinol arsonic acid, was sent to Harwell for further investigation. Greater quantities of some of the more promising resins were specially prepared for us by the Permutit Co., Ltd. A number of commercially available resins was also tested, including the carboxylic acid resin 'Zeo-Karb 226' and an α-hydroxy phosphonic acid resin supplied by Permutit.

The Portland tests were with fresh sea water which was pumped by a stainless-steel pump through a coarse filter into a head tank whence it flowed through a glass-wool filter into the test system. The connecting tubing and vessels were made of polythene, polyvinyl chloride or glass. The resin was held between two sintered glass disks 9 in. apart in a column of internal diameter 1 in. and subjected to upward-flowing sea water. At first, all the preparations showed only a low uptake, the maximum being 10 µg of uranium/g dry resin. However, the form of the resin proved to be critically important and a standard pretreatment procedure was evolved. The resins, initially in the damp H^+ form, were converted to the Na^+ form by 1·0 M sodium carbonate solution and then washed with redistilled water until fully swollen. Where particular mesh sizes were required the fully swollen resin was wet-sieved through stainless-steel mesh. After sizing it was reconverted to the H^+ form, with 0·5 M hydrochloric acid, washed with distilled water, dried for 48 h and bottled. Quantities, normally 2 g, were converted as required to the Na^+ form with 1·0 M sodium carbonate solution before placing in the column for testing. Although there was considerably greater uptake with several of the resins, only one reached values high enough to be of practical interest, namely, the arsonic acid resin. The early preparations of this material both rapidly lost weight in flowing sea water and were soluble in the sodium carbonate eluant used to remove the uranium. Improvements in the method of preparation which were made by Jones and Packham[9] at Teddington, and by Lane, Holdoway, Robinson and Willans at Harwell[10], increased the uniformity of product and enhanced matrix stability and general properties. The uptake of uranium by some typical organic materials is shown in Table 2.

Table 2. UPTAKE OF URANIUM FROM SEA WATER BY ORGANIC ABSORBENTS

Resin	Functional group	Time of contact (days)	Uptake µg/g of dry H^+ form
'Deacidite *FF*'	$-R_3NCl$	84	0·2
'Zeo-Karb 226'	$-COONa$	36	1·5
Polystyrene methylene phosphonic acid	$-CH_2PO(ONa)_2$	88	25
8-hydroxyquinoline	$-N=NC_9H_5N.ONa$	81	13
Resorcinol arsonic acid resin	$-AsO(ONa)_2$	112	1,010

Although the solubility shown by the original arsonic acid resin in sea water was largely overcome there still remained a steady loss of capacity which was traced to a slow hydrolytic attack on the carbon–arsenic bond[11]. This appeared to be an inherent weakness in any form of arsonic acid resin which seemed to exclude it as an absorbent for the economic extraction of uranium from sea water. Fortunately, alternative possibilities had arisen.

Although the concentration of uranium in the sea is far below the saturation level, deposition appears to be taking place at a rate equal to the rate of inflow from rivers. The mechanism is not properly understood but uptake by inorganic material seems to occur. In agreement with this, deposition of uranium from carbonate-containing waters in the Goodsprings District of Nevada has been attributed to absorption by hydrated ferric oxide and basic zinc carbonate. These considerations, coupled with our observation that ferruginous deposits in the filter on the inlet side of the sea-water plant at Portland contained some uranium, led us to investigate a number of inorganic materials as possible absorbents. They were precipitated on glass wool and packed into a glass column for testing. Sea water flowed upwards through the bed at the rate of 2·5 cm/min. Basic zinc carbonate, hydrated titanium hydroxide and certain lead compounds were the only materials which exhibited an effective uptake (Table 3).

Several other lead compounds showed comparable uptakes (lead naphthalene tetracarboxylate gave 1,074 µg/g in 35 days), but unfortunately all were unstable either in sea water or in the sodium carbonate eluant

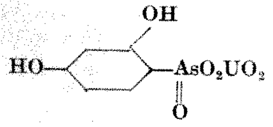
Table 3. UPTAKE OF URANIUM FROM SEA WATER BY INORGANIC ABSORBENTS

Compound	Time of exposure (days)	Uptake (μg/g of metal base)
Basic zinc carbonate	23	512
Titanium hydroxide	21	268
Lead sulphide	21	338
Lead pyrophosphate	21	479

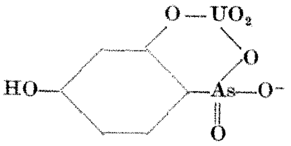
which led to a low uptake when re-used after elution. Moreover, the lead compounds and basic zinc carbonate dissolved too rapidly in the flowing sea water to be economically possible For example, basic zinc carbonate loses 0·5 μg zinc/ml. to sea water flowing at 2·5 cm/min through the bed. With titanium hydroxide, however, the loss under the same conditions was undetectable.

After appropriate contact with sea water, the arsonic acid resin and the inorganic materials listed in Table 3 contain between 0·02 and 0·1 per cent of uranium in terms of dry weight; that is, within the same range as the uranium content of the ores now being worked in the main uranium-producing territories.

The stoichiometry of the reactions between some of these materials and sodium uranyl tricarbonate solutions was examined. Saturation of the arsonic acid resin occurred with an arsenic/uranium atomic ratio of unity. Conductivity determinations on the arsonic acid monomer indicated that the uranyl complex is uncharged, and this is borne out by the behaviour of the resin itself which exhibits no cation exchange capacity when saturated. The structure of the complex is therefore more probably I than II:



I



II

Analysis of the wet, basic zinc carbonate precipitate invariably gave a ratio $Zn/CO_3 = 3$, implying the formulation $2Zn(OH)_2ZnCO_3$. This ratio is maintained at all uranium loadings. When absorption takes place from sodium uranyl tricarbonate solution, one mole equivalent of carbonate and two of bicarbonate are released into the solution for each mole equivalent of uranyl absorbed, so that carbonate is not taken up by the absorber. Hydrated titanium oxide behaves in the same way. The absorption mechanism can therefore be represented as follows:

$$M_x(OH)_y + UO_2(CO_3)_3^{-4} \rightarrow M_x(OH)_{y-2}O_2 . UO_2 + CO_3^{-2} + 2HCO_3^{-1}$$

Although this equation may be representative of the conditions when macro concentrations of sodium uranyl tricarbonate are used the absorption reaction in sea water may be different. Tracer experiments with uranium-233 in simulated sea water gave results which, for hydrated titanium oxide, were more indicative of the participation of a partially neutralized species $M_x(OHO^-)_y$.

During the course of this work a report was published describing Russian experiments on the extraction of uranium from natural saline waters containing 60 μg uranium/l. (that is, about 20 times sea water concentration) by absorption or co-precipitation processes[12]. Optimum results were obtained with calcium phosphate, alumino-gel and ferri-gel; titano-gel was also said to be satisfactory, uptakes being in the range 70–170 μg uranium/ml. of absorber. These results, which we have confirmed, indicate a different order of uptake compared with that from solutions with a uranium concentration as low as that in sea water. Those reagents which gave the highest uptakes from Russian lake-waters absorbed relatively insignificant amounts of uranium from sea water.

More recently experiments have been reported by Bayer[13] on the uptake of copper and uranium from sea water by various organic chelating agents containing, for example, the glyoxal *bis*-2-hydroxyanil grouping. The uptake of uranium from 100 l. of sea water from the Gulf of Naples was 50 μg for a bed 2 cm diameter and 30 cm deep, that is, < 50 μg/g absorbent. This is of the same order of uptake as we obtained with some other chelating agents (Table 2).

Properties of Selected Absorbents

Titanium hydroxide is an amorphous material the properties of which depend on the method of preparation. Two forms have been distinguished and designated *ortho* and *meta*: the first, a fully hydrated form, is obtained at room temperatures and the second, a partially hydrated form, is obtained after long standing in air at room temperature or by heating. Although no appreciable difference could be detected in the total uptake of uranium from sea water, the two forms exhibit considerable differences in rate of uptake. Most of the experiments described here were made with titanium hydroxide which was precipitated by means of caustic soda, but it was found, later on, that precipitation with ammonia resulted in a more active product. In some experiments, the absorbent was supported on glass wool, muslin or pumice; in others it was used alone, in the form of granules. The muslin was impregnated by soaking it first in titanium tetrachloride solution (15 per cent titanium tetrachloride in 15 per cent hydrochloric acid) for 5 min, draining off for 30 min and then soaking in 8 N caustic soda solution (A.R.) for 5 min. Before being put into sea water, it was washed with distilled water. Normally the muslin was attached to a frame suspended beneath a vessel in Portland Harbour. The experiments with glass wool were made in glass columns 16 in. × 2 in. with filtered sea water. Glass wool (60 g) was thoroughly wetted with the titanium tetrachloride solution (155 ml.), after which the 8 N caustic soda solution (250 ml.) was stirred into the mixture and stirring continued for 15 min. The treated glass wool plug was positioned and protected in the column by plugs of untreated glass wool at either end, allowed to drain and exposed to flowing sea water without further washing. Granular titanium hydroxide was made by mixing the same reagents in the ratio 155 ml. titanium chloride solution to 250 ml. 8 N sodium hydroxide while stirring vigorously to avoid an appreciable rise in temperature. The precipitate was washed by decantation with distilled water until the *p*H of the washings was less than 8. A slurry of the titanium hydroxide was poured on to trays so as to form a layer 0·5 in. thick and allowed to dry in air for 21 days. When the dried material was placed in distilled water it broke up into granules which could then be separated into different size ranges by sieving.

The uptake curves, shown in Fig. 1, are typical of the results obtained when the methods of preparation described here were used. The precipitate on muslin appeared to be rather finer and more disperse than that on glass wool and the absorption was faster but they both reached the same maximum uptake. Similarly, the smaller granules showed a faster initial rate of uptake than larger granules but, with each, absorption levelled off after a time and the larger granules gave a lower apparent saturation level. If the granules are assumed to be spherical, the ratio of the initial uptake rates proves to be roughly proportional to the ratio of the surface areas. On this model the outer layers of the particles would appear to be progressively saturated until, with the 0·3-mm diameter particles, for example, the thickness of the saturated zone reaches 0·03 mm in 20 days, whereafter the absorption rate falls off rapidly. The irregular shapes of the granules and their porous nature allow such a model to be regarded only as a crude representation; nevertheless it conforms with the idea that the larger the granule the greater is the volume which is inaccessible for uranium absorption.

Pergamon Press Publications

Journal of the Mechanics and Physics of Solids

Editor-in-Chief: **R. Hill, F.R.S.**, University of Cambridge

This bi-monthly journal contains original research work of particular interest to physical metallurgists, metal physicists and engineers. It deals with the theoretical principles which govern the work of those who produce or use construction materials, as well as experimental results.

Contents of a Recent Issue :
Creep and relaxation contraction ratio of linear viscoelastic materials – P.S. Theocaris; The effect of stress on the Lüders band velocity in niobium – H.Conrad and G.Stone; Stress distribution at the edge of an equilibrium crack – L.M.Keer; A displacement bound technique for elastic continua subjected to a certain class of dynamic loading – J.B.Martin; Interaction between an edge dislocation and a circular inclusion – J. Dundurs and T.Mura; A further note on the creep behaviour of circular plates – B.Venkatraman and P.G.Hodge, Jr.

Second-Order Effects in Elasticity, Plasticity and Fluid Dynamics

International Symposium, Haifa, Israel

Co-sponsored by the Israel Academy of Sciences and Humanities, and the Technion-Israel Institute of Technology, Haifa

Edited by **M.Reiner**, Member of the Israel Academy of Sciences and Humanities, Research Professor, Technion-Israel Institute of Technology, Haifa, and **D.Abir**, Associate Professor, Technion-Israel Institute of Technology, Haifa

Partial Contents :
On shock waves in hyperelastic media – D.R.Bland; The general measure of deformation – Z.Karni and M.Reiner; On theories of creep rupture – F.K.G. Odqvist; Survey on second-order plasticity – D.C.Drucker; Non-Newtonian flow and coiling of macromolecules – J.Schurz; Collocation method to study problems of cross-viscosity – M.K.Jain; On the uniqueness of solution in statics of continua with general differential stress-strain relations – L.Finzi; Normal pressure effects in the shearing of viscous liquids – R.D.Bell and R.C.L.Bosworth.
818 pages. £10.

Technology and Uses of Liquid Hydrogen

Edited by **R.B.Scott**, Cryogenic Laboratory, National Bureau of Standards, Boulder, U.S.A., and **W.H.Denton** and **C.M.Nicholls, A.E.R.E.**, Harwell

Contents :
Production of hydrogen – L.Mann; The liquefaction of hydrogen. Basic principles – P.C.Vander Arend; Description of existing liquefiers – Medium size – A.J.Croft, Large scale – P.C.Vander Arend; Thermal insulation, storage, transport and transfer of liquid hydrogen – H.B.Jacobs; Liquid hydrogen as a chemical fuel – R.Mulready and R.Anschutz; Liquid hydrogen as a coolant/propellant for a nuclear rocket – F.Edeskuty; The use of liquid hydrogen for the production of "Cold" neutrons inside a nuclear reactor – F.J.Webb; Liquid hydrogen bubble chambers for studying nuclear particle reactions – B.W.Birmingham and P.Hernandez; The separation of deuterium by the distillation of liquid hydrogen on a large scale – Sulzer process – J.Hänny, Linde process – W. Lehmer; Safety in the use of liquid hydrogen – D.Chelton.
520 pages. £6 ($14.00)

Partial Differential Equations of Mathematical Physics

S.L.Sobolev

Partial Contents :
Derivation of the fundamental equations; The equation for a vibrating string and its solution by d'Alembert's method; Integrals dependent on a parameter; Laplace's equation and Poisson's equation; The solution of the Dirichlet problem for a sphere; Properties of the potentials of single and double layers; The theory of integral equations; Green's function; Fourier's method; Integral equations with real, symmetric kernels; Vibrations of a rectangular parallelepiped; Harmonic polynomials and spherical functions.
International Series of Monographs on Pure and Applied Mathematics, Volume 56
440 pages. 100s.
Distributed in the U.S.A. by Addison-Wesley Publishing Company Inc., Reading, Massachusetts.

A Collection of Problems on Mathematical Physics

B.M.Budak, A.A.Samarskii and **A.N.Tikhonov**

Chapter Headings :
Classification and reduction to canonical form of second order partial differential equations; Equations of hyperbolic type; Equations of parabolic type; Equations of elliptic type; Equations of elliptic type $\triangle u+cu=-f$.
International Series of Monographs on Pure and Applied Mathematics, Volume 52
780 pages. 80s.

Handbook of Vacuum Physics

Edited by **A.H.Beck**, Engineering Laboratory, Cambridge

Volume 1

Part 1: *Vacuum technology as applied to continuously pumped systems – B.B.Dayton*; **Part 2**: *Properties of high vacuum pumps and design of vacuum pumping systems – T.E.Lucas*;
Part 3: *Leak detection and detectors – A.H.Turnbull.*
216 pages. Approx. 70s.

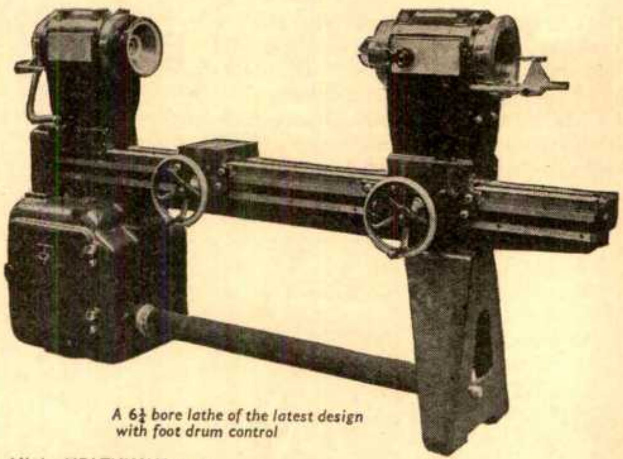
HEATHWAY
FOR GLASS WORKING LATHES



A 6½ bore lathe of the latest design with foot drum control

All the HEATHWAY range of lathes have the following features:

- ★ **Robust Construction and lasting accuracy**
- ★ **Efficient variable speed and easily accessible controls**
- ★ **Smooth traverses essential to good glassworking**

May we send you details of our range of lathes and equipment

Write or phone:

The HEATHWAY MACHINERY CO.,
UXBRIDGE ROAD, HILLINGDON, MIDDX.

Switzerland & Germany: Ernst Keller—Basle

The model also implies that granules of diameter less than 0·06 mm would be completely accessible.

It has been mentioned that the rate of uptake was higher when the titanium hydroxide had been precipitated with ammonia instead of caustic soda. Granules (14–24 mesh, diameter about 0·9 mm) produced by the ammonia route gave an uptake of 60 μg/g in one day when exposed to flowing sea water. This is more than ten times the initial rate obtained with the same size of granules prepared by the caustic soda method.

Titanium hydroxide is without detectable solubility in flowing sea water, but 0·1 μg/ml. was found in sea water which had been shaken with the precipitate for 72 h. No significant changes in specific uptake occurred after prolonged contact with sea water and after elution with M sodium carbonate solution. In the experimental work, the uranium content was frequently determined after complete dissolution of the sample, but for any large-scale extraction process selective leaching of the uranium would be necessary. Partition coefficients have been determined for a number of alkaline leaching solutions, and, in order to obtain results applicable to conditions of high dilution, trace concentrations of uranium-233 were used (Table 4).

Table 4. PARTITION COEFFICIENTS FOR ELUTION

	Partition coefficients (U per g Zn or Ti/U per ml.)	
Reagent	Basic zinc carbonate	Titanium hydroxide
0·25 M Na_2CO_3	168·0	1,311
0·5 M Na_2CO_3	96·4	602
1·0 M Na_2CO_3	49·8	206
0·25 M ammonium carbonate		45
0·5 M ammonium carbonate		1

Elution of uranium from basic zinc carbonate supported on glass wool is rapid with 1·0 M sodium carbonate, four or five bed volumes giving complete separation. But with titanium hydroxide, elution is slow; for example, less than 60 per cent of the uranium was removed by eight bed volumes of 1 M sodium carbonate eluant. A mixture of sodium bicarbonate (2 vol.) and sodium carbonate (1 vol.) gave 75 per cent elution in eight bed volumes and 1 M ammonium carbonate gave 65 per cent elution in two bed volumes and 93 per cent in eight. Dilute nitric acid is also a possible eluant for titanium hydroxide but ammonium carbonate appears to give the best results. The results in Table 4, obtained by batch equilibration at trace uranium concentration with the uranium initially in the aqueous phase, probably represent true equilibrium conditions since that for 1 M sodium carbonate was confirmed by approaching from the opposite side with titanium hydroxide containing natural uranium absorbed from sea water.

The solubility of titanium hydroxide in these eluants was determined: (*a*) by shaking with the precipitated floc for three days; (*b*) by passing the eluant through a bed of granular material at a flow rate of 1 cm/min.

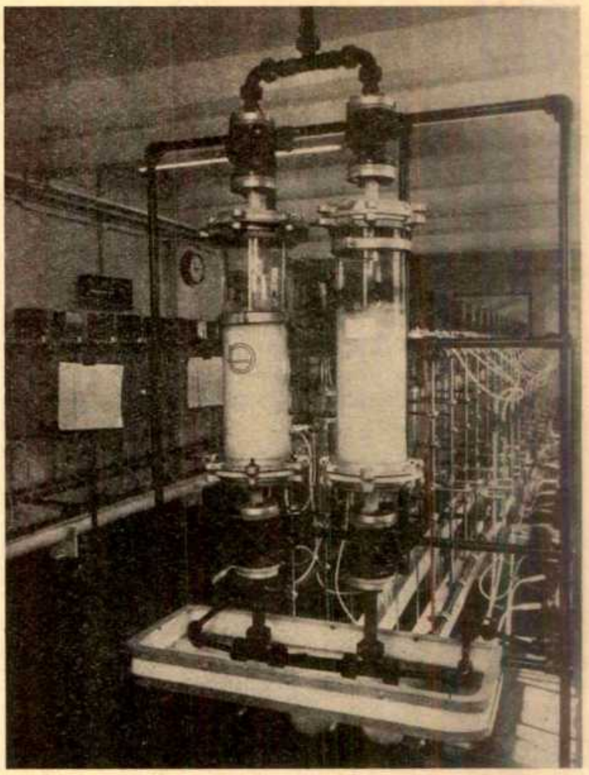

Fig. 2. Sea-water test equipment at Bincleaves Laboratory, Portland Harbour

Table 5. SOLUBILITY OF TITANIUM HYDROXIDE IN ELUANTS

Eluant	Solubility μg Ti/ml.
(*a*) $Ti(OH)_4$ precipitate shaken for 3 days	
1·0 M Na_2CO_3	0·48
0·5 M ammonium carbonate	1·4
1·0 M ammonium carbonate	14·1
(*b*) $Ti(OH)_4$ granules in flowing eluant	
1·0 M Na_2CO_3	0·1
1·0 M ammonium carbonate	11·4

The loss of absorbent in the eluant, although appreciable, would therefore not have a serious effect on the life of the bed.

Engineering Aspects

The engineering problems associated with the large-scale extraction of uranium from sea water are formidable but do not appear to be insoluble. Clearly it is desirable for the extraction plant to be sited so that it can be supplied with fresh uranium-bearing water by natural transport processes. In many coastal areas there is a residual drift superimposed on the purely oscillatory tidal motion which could maintain an adequate supply of uranium provided the rate of extraction was not too great. Certain ocean currents transport very large amounts of uranium. The volume of water transported by the Norwegian Current, which flows past the Orkneys and Shetlands, and along the coast of Norway towards the Arctic Sea, is about 3×10^6 m³/sec, which is equivalent to about 250,000 tons of uranium per annum; much greater quantities, carrying in excess of a million tons of uranium per annum, pass through the Florida Straits and the Japan Strait in comparatively narrow channels.

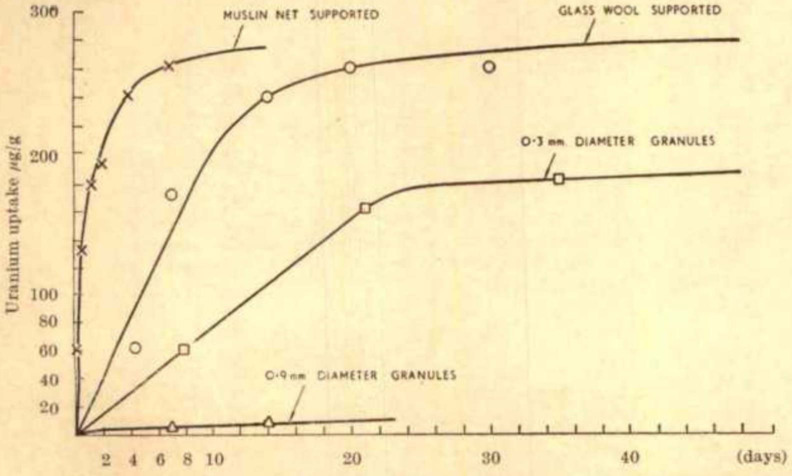

Fig. 1. Uptake of uranium from sea water by titanium hydroxide; typical results

Where there is a plentiful supply of fresh uranium-bearing water it would be possible to consider the advantages of means whereby only a small fraction of the uranium is extracted. Titanium impregnated muslin suspended beneath a vessel in Portland Harbour functioned in this way, giving very rapid uptake. Large-scale application of this technique, though possible in principle, would require a great deal of development to make it workable even before considering cost.

Other methods, in which the flow of sea water has to be channelled or controlled by engineering works, tend to require a high percentage extraction in an absorber system of specific design. Mass transport calculations have been made for different possible geometric arrangements of absorber, making the assumption that uptake was determined only by transport in the aqueous phase and that the diffusion coefficient of uranium species in sea water is about 3×10^{-6} cm²/sec. We obtained a value of $1{\cdot}8 \times 10^{-6}$ cm²/sec in the laboratory using the isotope uranium-233. The calculations showed that absorbers consisting of packs of parallel tubes lined with the absorbent placed across a channel would give a comparatively low yield unless the tubes were excessively long; for optimum absorption a considerable head of water would be required. Experiments were carried out in the southern (partially blocked) entrance to Portland Harbour using a cubic metre steel-framed cell containing asbestos cloth loaded with basic zinc carbonate folded over glass rods so as to give 1/8 in. spacing between layers. Uptake was slow and the percentage extraction was probably small, although this could not be accurately determined; saturation was reached after four weeks, yielding 0·25 g of uranium*.

The requirement for a greater head of water than could be obtained in a simple tidal channel led to an investigation of a fixed bed of absorbent particles operating against a head of sea water. Such a system, based on utilizing tidal energy in a manner similar to tidal power schemes, could be more easily visualized in engineering terms than any of the others considered. Two lagoons would be created, the sea water flowing into one on the rising tide, forming an upper lagoon, and out of the other, the lower, on the falling tide. The plant itself would consist of intermediate lagoons containing the packed beds, situated between the upper and the lower tidal lagoons. Sea water would flow into the plant lagoons from the upper lagoon, down through the packed beds and out along conduits into the lower lagoon. A difference in head of water would exist between the two lagoons which would depend on the level of the tide and the pressure drop through the bed. The beds would thus be operating continuously at all states of the tide, at a rate responding to the variations of head. The plant lagoons would be equipped with gates so that the flow of water could be cut off, enabling the beds to be eluted. The beds themselves would be partitioned so that sections could be eluted in a counter-current manner with a number of bed volumes of eluant, provided from the treatment plant located on the adjacent coast.

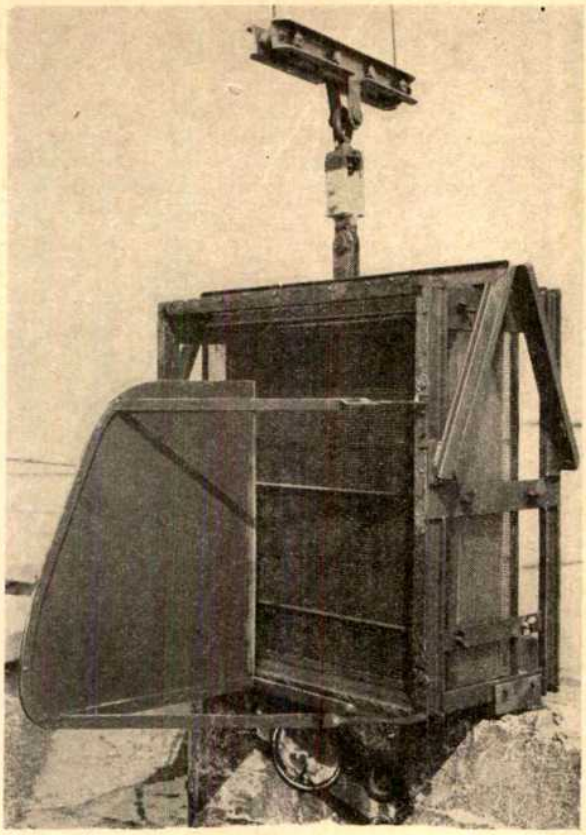

Fig. 3. Cell, 1 sq. metre cross-section, used in south entrance to Portland Harbour, showing frame bearing asbestos cloth impregnated with basic zinc carbonate

In order to obtain some idea of the problems and costs involved, a design investigation was made for a hypothetical plant operating in the Menai Straits. For this it was assumed that there is sufficient north-easterly drift of the water of the Irish Sea past Anglesey to maintain adequate supplies of fresh uranium-bearing water; there appears to be good reason for believing this but experiments were not carried out to establish it. The scheme would involve the construction of dams and sluice gates across the northern entrance between Anglesey and Great Orme's Head, and the division of the enclosed area of Beaumaris Bay into an upper lagoon and a lower lagoon by means of a dam and gates associated with absorber beds running in an approximately southerly direction from the neighbourhood of Puffin Island. A plant providing for the associated chemical operations would be located on shore at the southern end of the beds. Site investigations were not carried out and many assumptions had to be made regarding hydrological and geological factors and further uncertainty was introduced into the cost estimates by the novel engineering problems likely to be encountered. Fortunately we were able to make a comparison with results from the very thoroughly investigated Passamaquody Tidal Power Project through the courtesy of John W. Leslie, chief of the Engineering Division, Army Engineer Division, New England, U.S. Army Corps of Engineers, and this has enabled us to attach considerably greater confidence to our estimates of cost, particularly of the sea dams and gates. It would appear that the Menai site could produce almost 1,000 tonnes of uranium (1,300 short tons of U_3O_8) per annum, assuming adequate absorber performance, at a cost of £10,000–£20,000 per tonne (11–22 dollars per lb. U_3O_8). This is based on a twenty-year amortization; a lower unit cost would be achieved if the amortization period were extended from twenty to forty years. For comparison, the cost of extraction of uranium from shales has been estimated as 40–50 dollars per lb. U_3O_8 (ref. 14) and from granite as 100 dollars[15].

Performance of Titanium Hydroxide Absorber compared with Plant Requirements

The cost and performance of the absorber are, of course, key features. In making the estimate it was assumed that the active absorbent would be supported on low cost inert material in the form of small particles or granules.

---

* Mr. N. R. Daly, Atomic Weapons Research Establishment, Aldermaston, has kindly determined the isotopic ratios for this oceanic uranium, namely:

Sample	235/238	236/235	233/235	234/235
A	0·007255 ± 0·000012	0·00005	0·00005	0·0077
B	0·007250 ± 0·000008	0·00007	0·00006	0·0080
Normal for uranium	0·007258			0·0078

Table 6. PERFORMANCE OF BEDS OF SUPPORTED TITANIUM HYDROXIDE IN FLOWING SEA WATER

Support	Bed diam. (cm)	Bed height (cm)	Ti content (g)	Flow rate (cm/sec)	Uptake (mgU)	Time (h)	% Extraction
Muslin	7·6	33	13	0·3	1·215	24	33
Glass wool	5·1	61	12	0·04	0·306	33	93
Glass wool	5·1	61	12	0·04	1·3	166	79
Glass wool	5·1	20	5	0·2	0·821	26·6	62
Glass wool	5·1	20	5	0·75	0·926	7·25	70

A satisfactory bed filling in such a form has not yet been produced but data for beds containing titanium hydroxide supported on muslin and on glass wool are given in Table 6.

Although the glass-wool-supported beds give an adequate performance at flow rates within the range expected in the plant (0·55–0·79 cm/sec) they would not be suitable for large-scale operations both for physical and for economic reasons. It has been shown, however, that titanium hydroxide granules appear to behave as composite particles containing an inaccessible and therefore inert core surrounded by a layer of active absorbent. Beds of those granules should perform similarly to the beds of composite particles specified for the plant. Adequate flow rates were obtained for pressure drops likely to be obtained in the plant using comparatively small granules (mean diam. 0·1 cm), but a larger size would almost certainly be required in practice in order to avoid blocking of the bed.

The results in Table 7 show that uptake rates of the required order can be obtained with titanium hydroxide granules (diam. ~ 0·1 cm) and that a considerable latitude exists for optimizing the absorptive activity of the bed. If these unsupported titanium hydroxide granules were used in the plant instead of the cheaper supported material, the increase in cost would be about £5,000 per tonne (5·50 dollars per lb. U_3O_8). Although preliminary experiments with pumice particles about 1/8 in. in diameter were not very promising, it should be possible to find some other low cost support, such as hydrated silica granules, which is acceptable.

It has not been possible to extend the range of these experiments on account of the closure of the sea water laboratory at Portland, and the present results do no more than indicate that a reasonably favourable basis exists for further development. This would require a substantial effort in bed-material development and manufacture, elution technology and so on. In the Portland experiments blockage and contamination of the absorber beds were avoided by filtration of the sea water through glass wool; the engineering implications of this have not been taken into account and other, unforeseen, difficulties might arise. If we assume that operational difficulties can be overcome there appears to be some hope that the ocean can provide a ready supply of medium cost, if not low cost, uranium.

Table 7. COMPARISON OF EXPERIMENTAL RESULTS USING $Ti(OH)_4$ GRANULES WITH PLANT REQUIREMENTS

Size range of granules, 14–24 mesh (mean diam. ~ 0·1 cm)

Exp.	Bed depth (in.)	Pressure drop (ft.)	Flow rate (ft.³/ft.²/h)	Ti content (kg)	Uptake mgU in 24 h	% Extraction
			Experimental results for columns 1 in. in diameter			
A	25	16	180	0·105	0·071	3
B	1·9	0·25	70	0·008	0·026	3
C	0·5	0·067	70	0·002	0·12	14
			Extrapolated to plant, per sq. ft.			
A	15·6	4·0	70	13	8·3	7·7
B	15·6	2·0	70	13	38	24
C	15·6	2·0	70	13	150	~ 100
			Required in the plant			
		2·0	70–100	2·1	125	80

Notes: (1) The experimental uptake for *A* represents 1/7 of the uptake determined after 7 days.

(2) Absorbents *A* and *B* were made by sodium hydroxide precipitation, but different batches; *C* was by ammonia precipitation.

(3) Results for *B* and *C* are typical of several experiments.

(4) The extrapolations are on a simple linear basis; in *B*, it is assumed that transport in the aqueous phase is not rate determining. This seems to be approximately correct for the range of conditions specified in Table 7 although not for Table 6.

(5) The figures given for plant requirements are typical; satisfactory designs for other performances are not excluded. During actual operation there would be considerable variation depending on the state of the tide.

(6) The quantity of titanium given represents that actually used in the experiments with extrapolations according to note 4. The quantity given for the plant is the minimum needed for a four-day cycle of exposure followed by elution.

This article summarizes work which will ultimately be published in full. A RECONSTRUCTION OF THE CONTINENTS FOR THE UPPER PALÆOZOIC FROM PALÆOMAGNETIC DATA

By Dr. K. M. CREER

Department of Physics, University of Newcastle upon Tyne

AT a recent meeting on continental drift, sponsored by the Royal Society, I reported[1] some new palæomagnetic results from South American rocks and compared these with data from other Gondwanic continents.

It is my purpose here to describe a later stage of this work in which palæomagnetic data from the Gondwanic continents of South America, Africa and Australia are compared with those from the Laurasian continents of North America and Europe.

Since the preliminary results of my South American palæomagnetic work were published[2–4], I have carried out thermal and alternating-field demagnetizing experiments in order to determine more precisely the directions of the fossil magnetization by selectively destroying

Note. A reference number is given for each palæomagnetic south pole, followed by the latitude and longitude on the present latitude–longitude grid.

secondary magnetizations. Directions of magnetization and palæomagnetic south pole positions, calculated on the hypothesis that the geomagnetic field was, on the average, axial and dipolar during each geological epoch or substantial fraction thereof are listed in Table 1. The poles are plotted (●) in Fig. 1 and a polar wandering curve drawn. The striking feature of this curve is the pronounced shift during the Upper Palæozoic between poles 2 and 14. It is shown below that this feature is also present in the palæomagnetic records of Africa and Australia, the only other Gondwanic continents for which Palæozoic data are available. Furthermore, when the severe and widespread Permian remagnetization of Palæozoic red rocks in Europe and North America, recently proposed by Chamalaun and me[5], is taken into account this pole shift in the Upper Palæozoic is also evident in the palæomagnetic records of these northern continents. This can be clearly seen in Fig. 3, of which a fuller explanation is given later.

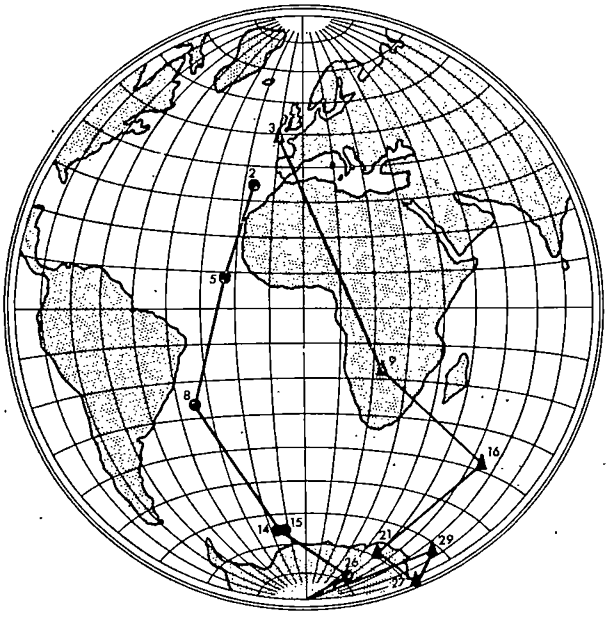

Fig. 1. Palæomagnetic south poles for South America (●) and Africa (▲). See Tables 1 and 2 for description of data. The grid represents the present latitude–longitude system

Palæomagnetic south pole positions used in this analysis are listed in Table 2, and notes are given in Table 3 of the sources of these data. An explanation of why certain data are omitted is given later.

First, let us consider the fit of South America and Africa. The shape of the polar wandering curve connecting Upper Palæozoic poles relative to Africa is similar to that for South America[1]. This means that there was no relative movement between these two continents, during this interval of geological time, and by superimposing these parts of the curves the position of these continents relative to one another and to the pole during the Upper Palæozoic may be determined. The polar wandering curves were fitted together by drawing them on a 50-cm globe. One of them was traced on to a transparent fibreglass hemispherical shell. This shell was then moved

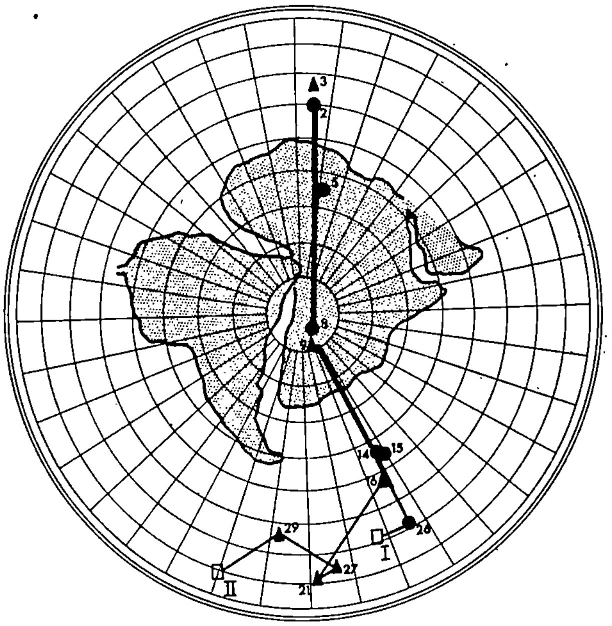

Fig. 2. A palæomagnetic reconstruction of the positions of South America and Africa for the Upper Palæozoic. The continents have been placed so that their polar wandering curves for the Upper Palæozoic coincide. The grid centre has no significance. I ●, South American poles; II ▲, African poles; ☐, present poles

over the surface of the globe until the Palæozoic portion of the curve drawn on it coincided best with the other curve drawn on the globe. The latter curve and also the outline of its continent were then traced on to the shell. Fig. 2 is a projection on a Lambert grid of tracings made on the shell. The polar wandering curves were fitted together by eye because more sophisticated mathematical treatment is not justified yet although it will have an important part to play later. At present we are not so much concerned with detailed fit but with the general overall pattern of distribution of the continents in the Palæozoic and of the movement of the pole across this. In the Upper Permian the two polar wandering curves separate and this indicates that, in the Mesozoic and later, South America and Africa no longer occupied the relative positions shown in Fig. 2 and that they were then drifting apart into their present positions. The fit obtained thus from palæomagnetic data is very close indeed to those which have been proposed by considering the shape of the coastline and from geological reasoning by several workers who have, in the past, advocated the hypothesis of drift and of whom perhaps the most famous are Wegener and du Toit. Recently the goodness of fit of these coastlines has been computed[6] and the best fitting positions so determined are barely distinguishable on a diagram the size of Fig. 2 from those deduced palæomagnetically.

The palæomagnetic data for South America and Africa are now compared with those from Europe and North America. In 1953, I made a palæomagnetic survey of rocks from Great Britain and hence deduced the first polar wandering curve for Britain[7]. Later, in collaboration with Irving and Runcorn, this curve was slightly modified and compared[8] with a similar curve deduced from North American rocks by Runcorn[9]. The shape of these curves is now familiar to most geophysicists and that for Britain is indicated by the broken line in Fig. 3, where north poles are plotted.

Let us now consider the data for the Palæozoic. My original Devonian pole *D* lies very close to the Permian (Nos. 18 and 19) and Carboniferous (Nos. 11 and 12) poles.

Last year Chamalaun and I carried out thermal experiments[5] on Old Red Sandstone rocks from the Anglo-Welsh cuvette and concluded that the natural remanence, although of exceptionally high stability, being unaffected by alternating magnetic fields of amplitude 1,000 œ or more, had most probably been acquired in the Permo-Carboniferous. We deduced that a much weaker magnetization which revealed itself after heating these rocks to 600° C and cooling them in zero magnetic field represented the true Devonian palæomagnetic field. This direction agreed with one previously obtained by Stubbs[10] for Old Red Sandstone lavas from Scotland. We now consider the true Devonian palæomagnetic pole for Britain to be that listed in Table 2 and plotted in Fig. 3 (pole No. 6).

At first we were reluctant to accept this result because it implied that many Russian and North American Devonian rocks the palæomagnetic directions of which agree with my original result for the Devonian from the Anglo-Welsh cuvette had also been remagnetized at the end of the Palæozoic. However, most of these Devonian rocks are red beds. During the Permian very many red beds were also laid down in North America, Western Europe and Russia, so that conditions then must also have been favourable for deposition of new red cement in older rocks which then happened to be near the surface, and thus for their remagnetization. To-day, the palæomagnetic record in tropical countries such as north-east Brazil where laterite is being formed is being slowly masked and even obliterated by magnetization in the direction of the present geomagnetic field of both old and of newly formed iron oxide minerals. During the Permian, the Palæozoic palæomagnetic records of the present northern hemisphere continents were very likely damaged and any directions which are nearly parallel to the Permo-Carboniferous palæomagnetic field from pre-Carboniferous red beds should be treated as suspect and should not be accepted until experiments similar to those described by Chamalaun and me have been carried out on them. The Middle Palæozoic poles for North America listed in Table 2 and used in this analysis have been determined from the magnetization of beds which were not appreciably reddened during the Permian. There is some evidence from the fold test that these magnetizations are post depositional, but even so it is likely that the magnetic age is pre-Carboniferous since the folding was pene-contemporaneous.

For these reasons I now accept that the solid lines in Fig. 3 represent polar movement relative to Western Europe and North America since the Middle Palæozoic. These paths are similar in shape to the path for South

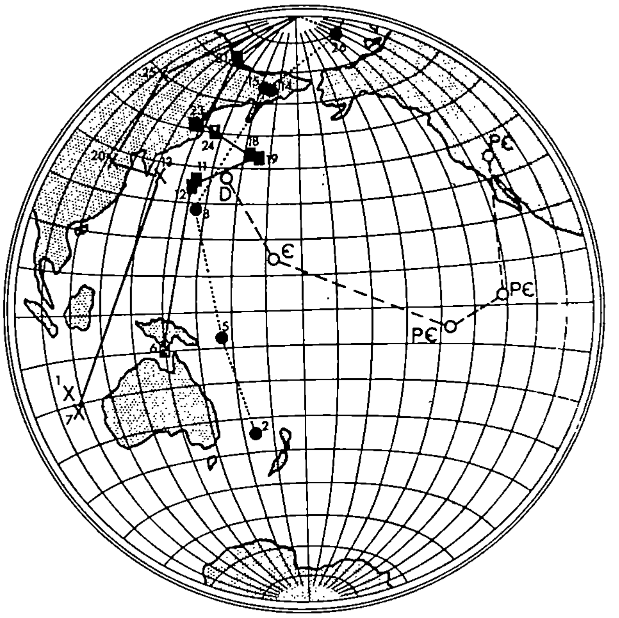

Fig. 3. Palæomagnetic north poles for Europe and Russia (■), North America (×) and South America (●). The new European Devonian pole No. 6 is displaced from the pole (*D*) used in constructing the original polar wandering curve (ref. 7) (– – O –), which connects Pre-Cambrian to Devonian poles. In the Mesozoic the original and new polar wandering curves for Europe are the same

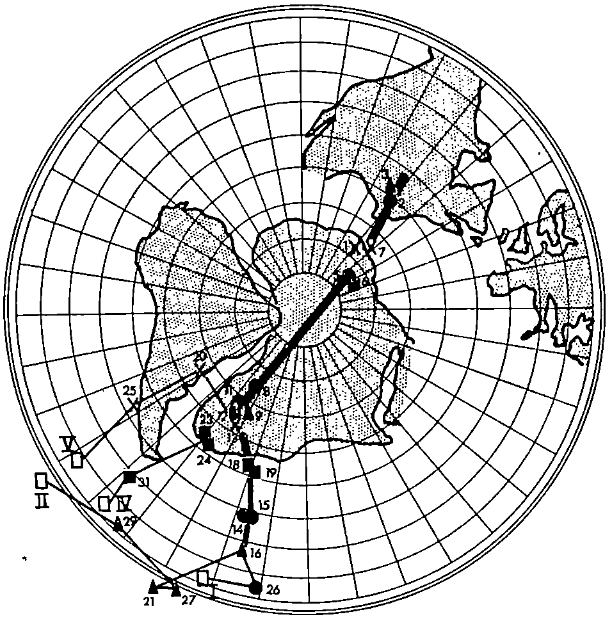

Fig. 4. Palæogeographic reconstruction obtained by fitting the Upper Palæozoic palæomagnetic south poles to the single curve marked by a thick line. The order in which the present continents broke away from the large landmass is indicated by the order in which the individual polar wandering curves separate from the main curve. The numbers are taken from Table 2. The symbols are defined by:

	Present pole	Ancient poles
South America	I	●
Africa	II	▲
Europe and Russia	IV	■
North America	V	×

The grid centre has no significance

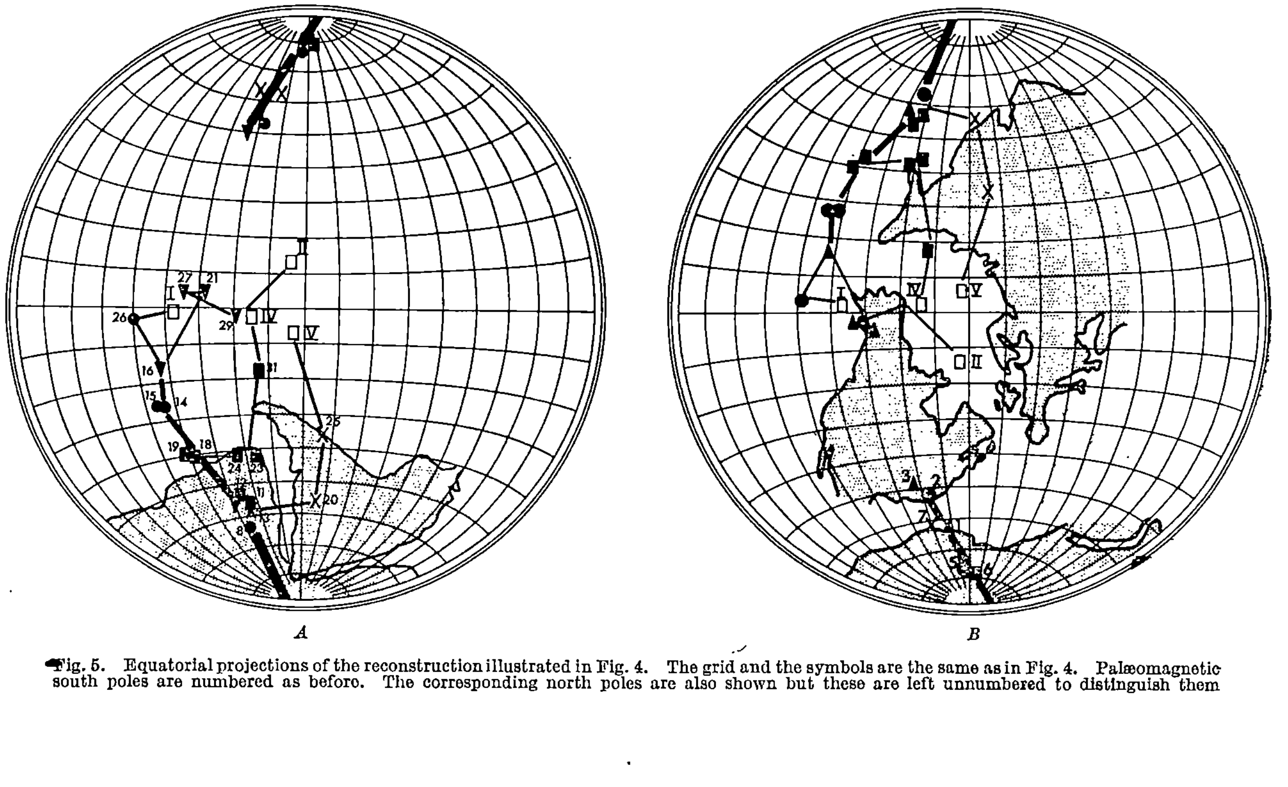
America, of which the north poles are also plotted in Fig. 3 and joined by a dotted line.

The palæomagnetic south poles for Europe and North America were plotted on the 50-cm globe and the Upper Palæozoic portions were fitted together by tracing on to the transparent hemispherical shell on which the curves for South America and Africa had been drawn. The outline of each continent was also traced on to the shell and thus a palæogeographic reconstruction of all these continents for the Upper Palæozoic was made. This and the common polar wandering curve were transferred on to polar and equatorial Lambert grids and the resulting diagrams are shown in Figs. 4 and 5. The polar wandering curves can be fitted remarkably well for the Upper Palæozoic and thus the continents must have then been very close to the positions shown, no relative movement having occurred during this interval of geological time. The fit of Western Europe and North America is similar to that proposed by many geologists, for example, du Toit, the Tethys sea occupying the broad space between Southern Europe and Gondwanaland.

In Figs. 5*A* and *B*, which are equatorial projections, the path of the palæomagnetic north pole is shown as well as that of the south pole. In this figure it has been supposed that Asia and Western Europe still comprised one single continent in the Palæozoic as they do at present. This is assumed tentatively in the absence of reliable Middle Palæozoic data for Siberia. In Figs. 3 and 4, it can be seen that the Russian Triassic, Permian and Carboniferous poles lie very close to the Western European for corresponding epochs. However, only a very small proportion of the Russian data are derived from rocks collected east of longitude 100° E, so there is really no evidence for or against the suggestion that Europe and Asia were then one large landmass.

It thus appears that the palæomagnetic south pole drifted across Gondwanaland from a position to the north-west of Africa, across Africa to a position off the coast of south-east Africa between the Silurian and Permian epochs with the continents reconstructed as shown in Figs. 4 and 5. The corresponding palæomagnetic north pole moved up the east coast of China and Siberia.

The disintegration of the Palæozoic landmass appears to have commenced in the Pennsylvanian at about the time when the Dwyka Tillites were being formed in South Africa. The North Atlantic then started to open up, and this is revealed in the palæomagnetic record by the separation of the North American polar wandering curve (V) from the main curve at poles 9 and 13 (Figs. 4 and 5). The European polar wandering curve (IV) separates from the main curve in the early Permian (poles 18 and 19), and this implies that Europe started to move relative to Gondwanaland narrowing the Tethys Sea. Later in the



A *B*

Fig. 5. Equatorial projections of the reconstruction illustrated in Fig. 4. The grid and the symbols are the same as in Fig. 4. Palæomagnetic south poles are numbered as before. The corresponding north poles are also shown but these are left unnumbered to distinguish them

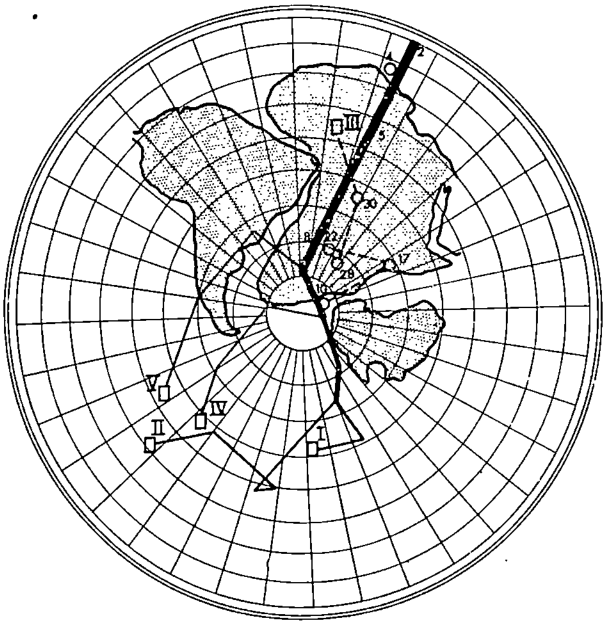


Fig. 6. Australian poles 4 and 10 have been fitted to the main curve and the outline of Australia constrained by these two points has been drawn in. Africa, South America and the polar wandering curves are all in the same positions relative to one another as in Fig. 4, but the grid centre is different from that of Fig. 4. The Australian palæomagnetic curve, for poles younger than 10, is shown by a broken line. Other symbols are as given in the key to Fig. 4

Permian (at pole 16), the South American (I) and African (II) polar wandering curves diverge, implying the South Atlantic then commenced to open out.

An attempt is now made to fit the Australian data to the pattern of events described here. Although much palæomagnetic work has been done on Australian rocks, few data exist for the Palæozoic and these have not been cleaned. The abundant Mesozoic and Tertiary data are obviously of no use in elucidating the arrangement of the continents in the Upper Palæozoic, which happens to be the crucial geological period. The two Upper Palæozoic poles, Nos. 4 and 10, show the large shift illustrated for the other continents (see Figs. 6 and 7) so that it is worth while attempting to fit the Australian data to the main curve. One possibility is to suppose that the Silurian-Devonian pole 4 is reliable and to fit it between the South American Silurian and Devonian poles, Nos. 2 and 5. The transparent shell on which the data of Fig. 4 had been drawn was then moved on the globe so that the pole for the Kuttung Series, No. 10, also lay on the main curve. It was found to lie between the Pennsylvanian and Permian portions (see Fig. 6). The pole path for Australia (III) for post-Kuttung time diverges from the main curve, and this implies that Australia must have started to drift relative to South America and Africa before the South Atlantic opened up between Africa and South America. This is the first important feature of this reconstruction. The second is that Australia is placed adjacent to Africa.

If the position of Australia is adjusted by making pole 10 coincide with the other Pennsylvanian poles at the knee of the main curve, Australia and Africa are found to overlap in regions where the geology is Pre-Cambrian, so such a reconstruction is ruled out and is not illustrated here.

It is stressed that the fit illustrated in Fig. 6 is based on only two not very well dated points and is given here principally to point out that at present the data for Australia are inadequate to reconstruct its position purely from palæomagnetism. Recently another attempt[13] has been made to reconstruct the Upper Palæozoic positions of Africa and Australia omitting to use pole 9 and using the antipole of 2 so that it is not surprising that a different result from that described here was then obtained.

Probably the best solution to the problem is illustrated in Fig. 7, which was made by adding Antarctica and Australia in the positions suggested by du Toit to the drawing on the transparent shell from which Fig. 4 was prepared, and this reconstruction of Gondwanaland is now compared with the Australian palæomagnetic data. The important thing to note is that pole 17 for the Permian Marine Latites now coincides with the South American and African Permian poles. Furthermore, Australia, Africa and South America start to separate and drift into their present positions at about the same time. Gondwanaland thus appears to have started to disintegrate in the Upper Permian. If we suppose that du Toit's reconstruction was the true one it follows that pole 10 is wrong. It is pertinent to note that the pole for the Marine Latites lay close to pole 10 before cleaning[20]. The Devonian-Silurian pole No. 4 lies on the main polar wandering curve, but rather closer to the Pennsylvanian knee than to the other Devonian poles (pole 5 is marked). The explanation for this might either be that these rocks need cleaning or that they are magnetically younger than their quoted age.

(Since this article was written, E. Irving has informed me, during a visit to this Department, that he has recently cleaned his Kuttung collection, and as a result has deduced a new palæomagnetic pole to replace pole 10. This new pole appears to agree with the reconstruction in Fig. 7.)

Finally it is necessary to comment on the accuracy of the palæomagnetic data used in this analysis. The biggest uncertainty is in the magnetic age of the rocks. Sedimentary rocks are frequently magnetized after deposition and their magnetic age may thus be less than their physical age. This is probably true in the case of pole 14 for South America. Fortunately the polar shift revealed by the palæomagnetism of Upper Palæozoic rocks is of considerable magnitude, spanning about 100° of arc. It persisted in roughly the same direction for about 200 million years, the average rate of movement being 0·5° per million years. Hence an inaccuracy in age of an individual pole does not appreciably affect the definition of a polar path. It does, however, mean that there must be some doubt concerning the rate at which the pole moved along this path. It is possible, for example, that a large part of the movement might have occurred much more rapidly

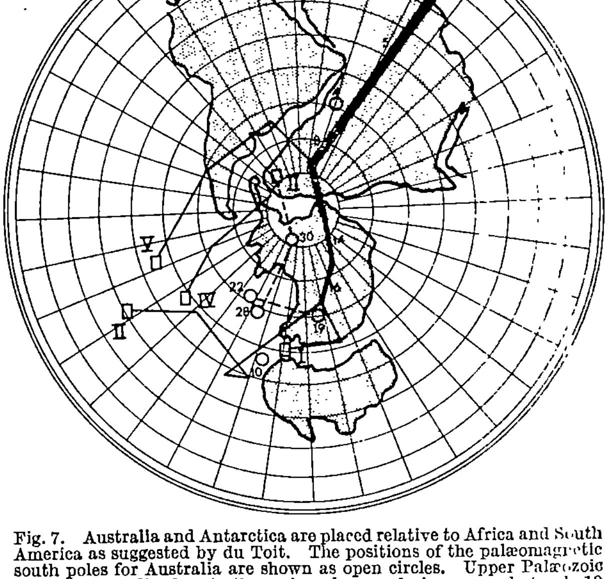

Fig. 7. Australia and Antarctica are placed relative to Africa and South America as suggested by du Toit. The positions of the palæomagnetic south poles for Australia are shown as open circles. Upper Palæozoic poles 4 and 19 lie close to the main polar wandering curve, but pole 10 does not. The pole path between the Mesozoic and the present for Australia is shown by a broken line

than the average rate of 0·5° per million years during a fraction of the total time apparently available. In future, when more well-dated data have been obtained, thus defining the time-scale, it should be possible to determine magnetic ages of Upper Palæozoic rocks from the position of their poles on the master curve.

The standard error of each of the poles listed in Table 2 is less than about 10°. For more details the reader should consult the references noted in Table 3, but he should beware of placing too much reliance on values of circles of confidence given in papers or lists of poles without carefully enquiring how they were calculated, since no single method of doing this has been generally agreed. Frequently the effects of secular variation of the ancient geomagnetic field have not been averaged out because inadequate thicknesses of rock were sampled. Thus the quoted circles of confidence are not realistic because the poles quoted are not true palæomagnetic poles in that they do not coincide with the ancient geographic pole. Sometimes authors have taken no account of systematic errors due to partial remagnetization, and when samples have been collected from too small an area the effects of tectonic movement have not been properly considered.

Lower Palæozoic data have not been considered in this analysis because few are reliable. I am now carrying out more thermal demagnetization experiments on British and South American Cambrian formations and I hope to extend this analysis back in time to the beginning of the Cambrian in the near future.

The prime purpose of this analysis has not been to deduce an exact palæogeographical reconstruction for the Upper Palæozoic, but rather to illustrate that when the reliability of palæomagnetic data is carefully considered, those data thought to be the most reliable fit a rather simple overall pattern which does not conflict unduly with geological evidence. One important result of this analysis is that it illustrates the importance of carrying out much more palæomagnetic work on Palæozoic rocks which have been rather neglected in past studies, and of taking great pains to detect stable secondary magnetization.

NEWS and VIEWS

Science Policy Research in the U.S. Library of Congress : Dr. Edward Wenk, jun.

DR. EDWARD WENK, JUN., has been appointed chief of a newly created Science Policy Research Division in the Legislative Reference Service at the Library of Congress and will also serve as special adviser to the Librarian in Science and Engineering as from September 28. Dr. Wenk is at present technical assistant to the Director of the Office of Science and Technology in the Executive Office of the President. He has also been serving as Executive Secretary of the Federal Council for Science and Technology. In his new post, Dr. Wenk will serve in the Legislative Reference Service as a Congressional consultant in scientific and technological developments that affect public policy, and he will also serve the Library as a whole, in his capacity as special adviser to the Librarian and as co-ordinator of science information services furnished to the Congress. Dr. Wenk served in the Legislative Reference Service of the Library of Congress from 1959 until 1961 as senior specialist in science and technology. He resigned in 1961 to join the White House staff as assistant to the President's Science Adviser and moved to the President's Office of Science and Technology when it was established in 1962. In addition to serving also as the Federal Council's executive officer, he served as staff specialist in scientific man-power, long-range planning, and oceanography. A graduate of the Johns Hopkins University, where he gained a B.E. degree in civil engineering in 1940, Dr. Wenk holds an M.Sc. degree in applied mechanics from Harvard University (1947), and a D.Eng. degree in civil engineering from Johns Hopkins University (1950). He served in the U.S. Navy during the Second World War and received a Navy Civilian Meritorious Service Award. From 1942 until 1956 he was a naval research scientist and research administrator for the David Taylor Model Basin in Washington, and from 1956 until his first appointment to the Library of Congress in 1959 he was chairman of the Department of Engineering Mechanics at the South-west Research Institute in San Antonio, Texas. Dr. Wenk has been a special lecturer at the University of Maryland, Harvard University, Massachusetts Institute of Technology, Virginia Polytechnic Institute, Purdue University, Yale University, and the University of Texas.

Director of the Water Pollution Research Laboratory, Stevenage : Dr. B. A. Southgate, C.B.E.

DR. B. A. SOUTHGATE, director of the Department of Scientific and Industrial Research Water Pollution Research Laboratory at Stevenage, is to retire at the end of March 1966. Dr. Southgate first joined the Water Pollution Research Organization as a chemist in 1929. Before the Second World War he worked on the development of methods for the treatment of industrial effluents and conducted two major surveys of estuaries. The first, a detailed examination of the effects of pollution on the Tees Estuary, set a pattern for many similar surveys in various parts of the world; the second, on the Mersey Estuary, showed that pollution by untreated sewage was not responsible for siltation of the navigable channels. In 1940 the first central Water Pollution Research Laboratory was set up—though in temporary premises—and in 1943 Dr. Southgate was appointed director. His book on *Treatment and Disposal of Industrial Waste Waters*, published in 1948, was an outstanding contribution to the literature on the subject, and showed clearly his unrivalled knowledge of the field. The activities of the Station expanded steadily after the War and in 1954 it was transferred to a permanent new laboratory (at Stevenage). Under Dr. Southgate's leadership, early empiricism in the research has been replaced by a much more fundamental approach. The benefits are to be seen particularly in the successful outcome of a recently completed survey of the effects of pollution on the Thames Estuary, in which methods have been worked out for predicting the effects on the condition of the water of any given discharge, thus enabling the best way of dealing with the pollution problem to be assessed accurately.

Mr. A. L. Downing

Mr. A. L. Downing is to succeed Dr. Southgate as director of the Water Pollution Research Laboratory. Until Dr. Southgate's retirement in 1966 Mr. Downing will act as deputy director. Mr. Downing, who is thirty-eight, was born at Trentham, Stoke-on-Trent. He was educated at Arnold School, Blackpool, and was awarded a County scholarship to the University of Cambridge where he read natural sciences. Mr. Downing's first appointment within the Department of Scientific and Industrial Research was to Water Pollution Research in October 1946. In October 1947 he was seconded to the Ministry of Agriculture, Fisheries and Food for research at Lowestoft on the effects of radioactive materials on fish. In December 1948 he joined the staff of the Government Chemist in London while studying for an external degree at the University of London, returning to the Water Pollution Research Laboratory in August 1950. Mr. Downing is at present in charge of a large group of sections concerned primarily with biochemical engineering.

Neurophysiological Feedback Research in the National Physical Laboratory : Dr. Thomas B. Mulholland

Dr. Thomas B. Mulholland, jun., of the Veterans Administration Hospital, Bedford, Massachusetts, has been awarded a Carnegie Institution fellowship grant of 12,000 dollars for a year's research on stimulus-brain feedback systems, at the National Physical Laboratory, Teddington. Dr. Mulholland graduated from Tufts College in 1951 and then studied at Clark University, where he received an M.A. in 1952 and a Ph.D. in 1956. He became a post-doctoral trainee at the Veterans Administration Hospital in Bedford in 1956, and is still associated with that hospital. In addition, he is a lecturer in the Division of Continuing Education at Boston University and a lecturer at Clark University. Dr. Mulholland's field is psychology. For the past two years he has been investigating the development of a stimulus-brain feedback system and its application to a variety of psychological and neuropsychological problems.

Mathematics in the University of Strathclyde: Prof. W. D. Collins

The University of Strathclyde has announced the appointment of Dr. W. D. Collins, at present lecturer in applied mathematics in the University of Manchester, to a new professorship in mathematics, from January 1, 1965. Dr. Collins graduated with first-class honours in mathematics at the University of London in 1953 and was awarded the degree of Ph.D. in 1956. He began his career as a scientific officer with the Admiralty Research Laboratory, Teddington, in 1956. In 1957 he was appointed to a lecturership in applied mathematics at King's College, Newcastle upon Tyne, a post which he held until 1961, when he joined the staff of the University of Manchester. For nine months in 1963 he was on leave of absence as a research associate in the Division of Electromagnetic Research at the Courant Institute of Mathematical Sciences, New York University. Dr. Collins's main research interests are in solid mechanics, diffraction theory and methods of applied mathematics, in particular the investigation of integral equations and their application.

Veterinary Microbiology and Parasitology in the Royal Veterinary College, London : Prof. A. O. Betts

Dr. A. O. Betts, at present lecturer in animal pathology in the University of Cambridge, has been appointed to the newly established chair of veterinary microbiology and parasitology in the Department of Pathology at the Royal Veterinary College, London. He himself graduated from the Royal Veterinary College in 1949. Following this he became a research student in the Department of Animal Pathology, Cambridge, where he gained his Ph.D. in 1953. He was appointed demonstrator in that Department in 1952 and became a lecturer in 1956. He was awarded a Commonwealth Fund fellowship in 1955 and studied at the New York State Veterinary School at Cornell, and other centres. His research was at first centred round respiratory diseases of pigs and later his interests spread to include many virus diseases of animals. He has been a pioneer in the study of enteroviruses of domestic animals. He is a member of the World Health Organization's Committee on the Classification of Veterinary Viruses and was co-chairman of a conference on "Comparative Virology" held in New York in 1962 under the auspices of the New York Academy of Sciences. In addition to a number of visits to the United States he has also lectured at several veterinary research establishments on the continent of Europe.

Recruitment of Graduates to School Teaching

The report of the Sub-Committee on Recruitment to School Teaching of the University of Glasgow Appointments Committee notes a disturbing decline in the proportion of men graduates of Glasgow (honours and ordinary) and of women with ordinary degrees in arts and science entering teaching in 1962 (Pp. 16. Glasgow : The University, 1964). The proportion of men graduates with ordinary degrees in science who enter teaching has decreased by 17·5 per cent since 1959, and that of women by 12 per cent since 1960. The Sub-Committee does not consider that salary is now an important deterrent, but the apparent lack of good prospects for promotion in teaching is a serious deterrent and the very considerable change for the better since 1961 is not yet sufficiently widely known. It is also critical of the rigidity of present regulations on certification and recognition, and the Sub-Committee believes that the postgraduate year in a College of Education may also be a deterrent owing to misunderstanding of the nature of the courses, doubts as to necessity or value of the training, and the prolonged dependence on Government grants or parental resources. The limitations of day-school teaching can also deter some, through fear of losing their specialist knowledge, risk of staleness and lack of contact with the adult world. The report makes several suggestions for remedying the defective information position by better descriptive literature and talks to students, but also suggests experiments with trial runs. The defects in the system itself must await Government action, and, while welcoming the Ministry of Education's consultation of the appointments officers of the universities and its commissioning of an enquiry by the Social Survey into what undergraduates know and think about prospects in the teaching profession, and what makes school teaching attractive or unattractive to them, the Sub-Committee recommends immediate attention to three particular defects. First, early consideration should be given to the advisability of pay during training. Secondly, the regulations relating to the certification of teachers should be speedily revised to bring them up to date and make them more flexible. Thirdly, the problem of promotion should be tackled appropriately without delay to create a more uniform and smoothly working system with some real incentive to the able young teacher.

Medical Schools of the World

The third edition of the *World Directory of Medical Schools* will be of great value to everyone who is either concerned with medical education or is planning that kind of education for himself (Pp. 348. Geneva: World Health Organization; London: H.M.S.O., 1963. 20 Sw. fr[illegible] 35*s*.; 6.75 dollars). It provides detailed information about the salient features of undergraduate medical education in 87 countries of the world, the material having been provided by the health authorities of the countries concerned or by the medical schools themselves. To this has been added information about the admission of foreign students to medical schools and about the conditions which govern medical practice by nationals with foreign qualifications or by foreigners who have qualified in the country concerned. There is also information about the laws which govern medical practice in some countries which have no medical schools. Tables show the number of years of medical education required in each country and other conditions that must be fulfilled before a licence to practice is granted. It is interesting to note that, while most countries require a practitioner to complete at least one year of experience in a hospital before he may practise, some countries, such as China and the Sudan, require him to complete two years of such experience; Austria alone requires him to complete three. In some countries one of the years of postgraduate experience is devoted to rural or State service or to specialization and teaching. The *Directory* also supplies data about the population of the countries concerned, the number of medical schools and physicians, and the number of students who enrol and are admitted and who graduate. An interesting appendix compares the numbers of medical, dental and veterinary schools. It may surprise some readers to learn that whereas the United Kingdom has 6 veterinary schools, Japan has 14, the U.S.S.R. 23, the United States 18 and India 16. A study of these pages will enable the reader to obtain what is, in effect, an overall picture of medical education all over the world. It is clear that the total number of years spent, including primary and secondary education, before practice is allowed varies little all over the world. In most countries primary and secondary education followed by pre-medical, medical and hospital experience add up to some 19–20 years of training, while in the Lebanon and the United States the total is 21 years. The time devoted specifically to medical education varies little, being usually 4–6 years.
